**Abstract.** Supercooled large droplet (SLD) icing can occur behind the protected surfaces of an aircraft and create severe aerodynamic disturbances, which represent a safety hazard for aviation. Liquid water content (LWC) measurements in icing conditions that contain SLDs require instruments that are able to sample unimodal and bimodal droplet size distributions with droplet diameters from 2 to 2000  $\mu\text{m}$ . No standardized detection method exists for this task. A candidate instrument, which is currently used in icing wind tunnel (IWT) research, is the Nevzorov probe. In addition to the standard 8 mm total water content (TWC) collector cone, a novel instrument version also features a 12 mm diameter cone, which might be advantageous for collecting the large droplets characteristic of SLD conditions. In the scope of the two EU projects, SENSors and certifiable hybrid architectures for safer aviation in ICing Environment (SENS4ICE) and ICE GENESIS, we performed measurement campaigns in SLD icing conditions in IWTs in Germany, Austria and the USA. We obtained a comprehensive data set of measurements from the LWC sensor, the 8 mm cone sensor and the 12 mm cone sensor of the Nevzorov probe, and from the tunnel reference instrumentation. In combination with measurements of the particle size distribution, we experimentally derive a collision efficiency curve that is based on a suitable functional form for the new 12 mm cone for median volume diameters (MVDs) between 12 and 58  $\mu\text{m}$  and wind tunnel speeds from 40 to 85  $\text{m s}^{-1}$ . Knowledge of this

curve allows us to correct the LWC measurements of the 12 mm cone ( $\text{LWC}_{12}$ ) in particular for the inevitably high decrease in collision efficiency for small droplet diameters. In unimodal SLD conditions, with MVDs between 128 and 720  $\mu\text{m}$ ,  $\text{LWC}_{12}$  generally agrees within  $\pm 20\%$  with the tunnel LWC reference values from a WCM-2000 and an isokinetic probe. An increase in the difference between  $\text{LWC}_{12}$  and the WCM-2000 measurements at larger MVDs indicates better droplet collection properties of the 12 mm cone. Similarly, the favorable detector dimensions of the 12 mm cone explain a 7% enhanced detection efficiency compared to the 8 mm cone; however this difference falls within the instrumental uncertainties. Data collected in various bimodal SLD conditions with MVDs between 16 and 534  $\mu\text{m}$  and LWCs between 0.22 and 0.72  $\text{g m}^{-3}$  also show an agreement within  $\pm 20\%$  between  $\text{LWC}_{12}$  and the tunnel LWC, which demonstrates the suitability of the Nevzorov sensor head with the 12 mm cone for measurements of LWC in Appendix O icing conditions.

## 1 Introduction

The fatal accident of an ATR 72 aircraft near Roselawn, Indiana, in 1994 (National Transportation Safety Board, 1996; Marwitz et al., 1997) prompted the Federal Aviation Administration (FAA) and European Union Aviation Safety Agency

(EASA) to review the existing regulations for flight in icing conditions. It also initiated numerous research activities which aimed to study the occurrence and the distributions of supercooled large droplets (SLDs), which are defined as droplets with diameters larger than 100  $\mu\text{m}$ . SLDs mostly occur as part of bimodal droplet size distributions, i.e., a significant number of small droplets are present alongside the SLDs (Cober and Isaac, 2012). Cober et al. (2009) separated SLD conditions into four subsets based on the maximum droplet size and the median volume diameter (MVD) of the droplet size distribution (DSD). Icing conditions which contained drops with diameters larger than 500  $\mu\text{m}$  were classified as freezing rain (FZRA), and conditions without drops larger than 500  $\mu\text{m}$  were classified as freezing drizzle (FZDZ). Furthermore, they distinguished between the conditions with an overall MVD smaller than 40  $\mu\text{m}$  (representing a strong, small droplet mode) and those with an overall MVD larger than 40  $\mu\text{m}$  (representing a strong, large droplet mode). They also found that the occurrence of SLD conditions is in most cases limited to a temperature range from  $-25$  to  $0^\circ\text{C}$  and to a relatively low liquid water content ( $< 0.44 \text{ g m}^{-3}$ ). Based on this analysis they developed an engineering standard that aircraft need to comply with in order to operate in SLD conditions. This standard was eventually added to part 25 of the Federal Aviation Regulations (14 CFR) and to EASA's "Certification Specifications for Large Aeroplanes" (CS-25) as Appendix O (Office of the Federal Register, 2016; EASA, 2021); hence the SLD conditions which fall within its specifications are also called Appendix O conditions. Prior to the addition of Appendix O, aircraft were only certified for flying in icing conditions that fall into Appendix C of 14 CFR part 25 (Appendix C conditions). The droplet distributions of Appendix C conditions consist of droplets with a mean effective diameter smaller than 50  $\mu\text{m}$  and do not contain SLDs. Established instruments for measuring the liquid water content (LWC) in Appendix C conditions include the King probe (King et al., 1978), the WCM-2000 multi-element water content system (Steen et al., 2016) and the Nevzorov probe (Korolev et al., 1998, 2007, 2013; Schwarzenboeck et al., 2009; Strapp et al., 2003). In icing wind tunnels (IWTs), rotating cylinders of various diameters (Stallabrass, 1978; Orchard et al., 2019) and icing blades (Ide, 1990) are used. In the absence of standardized measurement methods, many of these techniques are also employed to measure Appendix O conditions. However, since the DSDs of Appendix O conditions span a significantly wider range of droplet sizes than Appendix C conditions, the uncertainties associated with the measurement principles are significantly larger and have not yet been discussed in detail in the literature.

In this work, we assess the performance of a Nevzorov probe in IWT conditions that contain SLDs. Specifically for the purpose of measuring SLDs, Environment and Climate Change Canada (ECCC) designed a Nevzorov sensor head with a second, larger total water content (TWC) collector cone with a diameter of 12 mm, which was subsequently pro-

duced by the manufacturer of the Nevzorov probe, the Canadian company SkyPhysTech Inc. The new sensor head was tested by the ECCC in the altitude icing wind tunnel of the National Research Council of Canada (Oleskiw et al., 2001; Orchard et al., 2018, 2019) and employed during the In-cloud Icing and Large-drop Experiment (ICICLE) flight campaign (Bernstein et al., 2021).

Apart from the larger diameter, the interior of the new 12 mm cone also differs from that of the standard 8 mm Nevzorov cone. In order to increase the heated surface area and to prevent splashing and bouncing of particles, the inside of the 12 mm cone was given a bell-shaped form, such that the cone attains a depth of approximately 14.5 mm. At the inlet, the angle between the interior wall and the frontal area is  $30^\circ$ , the same as for the 8 mm cone (see Fig. 1). An additional advantage of the new cone is the larger sample area, which provides better sampling statistics.

However, due to its larger size, the 12 mm cone has a lower collision efficiency for small droplets, which has not yet been characterized. In this work, we experimentally derive this collision efficiency and verify the new sensor's suitability to cover the large droplet size range of Appendix O conditions. The measurements on which we base our study were conducted in the scope of two EU projects, which we introduce in the following section. Subsequently we describe the principle of operation of the Nevzorov probe, present the full set of measurements and derive a collision efficiency curve for the 12 mm cone. In the final sections we analyze the performance of the Nevzorov probe in unimodal and bimodal SLD conditions and investigate the errors that are introduced when correcting for droplet collision efficiency with the MVD approximation.

## 2 The SENS4ICE and ICE GENESIS research projects

In the framework of Horizon 2020, the European Union funded two projects, SENSors and certifiable hybrid architectures for safer aviation in ICing Environment (SENS4ICE) and ICE GENESIS, with the goal to advance the capabilities of measuring, detecting, and modeling SLD icing conditions and ice accretion. The SENS4ICE project aims to develop an airborne hybrid ice detection system that is able to detect and differentiate between Appendix C and Appendix O conditions (Schwarz et al., 2019; Schwarz, 2021; Deiler, 2021). The system uses the measurements of direct icing sensors in combination with data that are obtained by monitoring the aircraft's flight characteristics (SENS4ICE, 2021). The ICE GENESIS project on the other hand focuses on developing advanced tools for the 3D simulation of SLDs and snow icing conditions (ICE GENESIS, 2021). In both projects IWTs play a key role for the validation of the technology that is developed. The participating IWTs consequently enhanced and adapted their spray system for Appendix O conditions. The production of Ap-

**Figure 1.** (a) Nevzorov probe in the Braunschweig IWT (BIWT) with the new sensor head, which features an LWC sensor (top), an 8 mm TWC collector cone (middle) and the new 12 mm TWC collector cone (bottom). The sensor head contains only one reference sensor, which is positioned on the downwind side of the banneret that constitutes the top of the sensor head. (b) Cross section through the new Nevzorov sensor head and approximate dimensions of the sensors. The Nevzorov sensor heads are handmade; therefore small differences may exist between sensor heads that are nominally the same model.

pendix O conditions is especially challenging because SLDs sediment faster than smaller droplets and take longer to reach the free-stream tunnel velocity and temperature (Orchard et al., 2018). Furthermore, the low LWC constraints of Appendix O complicate the generation of a continuous and homogeneous droplet spray (Ferschitz et al., 2017). In the framework of SENS4ICE, Appendix C and O conditions produced in three different IWTs were compared by using measurements with the Nevzorov hot-wire probe and the Cloud Combination Probe (CCP). Within ICE GENESIS, several campaigns were performed in the Rail Tec Arsenal (RTA) IWT with these and similar airborne instruments. We report on the measurements that were collected in Appendix C and O conditions as part of SENS4ICE and ICE GENESIS at the Goodrich IWT of Collins Aerospace in Ohio, the RTA IWT in Vienna, Austria, and the Braunschweig IWT (BIWT) in Germany. We selected these three IWTs for this study, because taken together they are able to produce a very large range of icing conditions with distinctively different spray systems (e.g., rotating nozzles for the production of freezing rain at RTA; Breitfuß et al., 2019). The usage of three wind tunnels also helps us to mitigate the influence of possible biases that are only present in one facility. Another criterion for the selection of the wind tunnels was the requirement to have DSDs available for all test points. The technical parameters of the three IWTs are listed in Table 1, and schematics are shown in Fig. 2. The Collins IWT and the RTA IWT are well-established facilities that have been involved in icing research for decades (Herman, 2006; Collins Aerospace, 2021; Haller, 2005). Breitfuß et al. (2019) provide detailed information about the Appendix O conditions that are produced at RTA. The BIWT is a new facility whose design is described in Bansmer et al. (2018). The tunnel was used for numerous research activities on ice crystal and supercooled liquid water icing in recent years (Esposito et al., 2019; Knop

et al., 2021). In 2019 and 2020 the tunnel spray system was upgraded to include the capability to create Appendix O conditions. All three wind tunnels have been calibrated per SAE ARP 5905 (AC-9C Aircraft Icing Technology Committee, 2015). For the characterization of the 12 mm Nevzorov TWC cone, we evaluate measurements of LWCs from these three tunnels in combination with the DSD measurements from the CCP and the tunnel reference instrumentation.

### 3 The Nevzorov probe's principle of operation

The Nevzorov probe is the primary instrument that we investigate in this work. Therefore we describe its principle of operation and the procedure to derive LWCs from its measurements. The Nevzorov probe belongs to the category of hot-wire instruments (SkyPhysTech Inc., 2020; Korolev et al., 1998). Such instruments contain heated sensing elements which are maintained at a constant temperature. Heat losses of these sensing elements are caused by convection and by impinging droplets which are heated and evaporated. From the power that is needed to maintain a constant temperature of the sensing elements, the LWC and the TWC are estimated. In order to differentiate between convective heat losses and heat losses that are due to impinging water, the Nevzorov contains two types of sensors. Collector sensors are exposed to the airflow and the droplet spray. Their heat losses are due to evaporation and convection. The reference sensor on the other hand is protected from droplet impingement, and its heat loss is solely due to convection. The Nevzorov probe outputs the voltages  $V_c$  and currents  $I_c$  of the collector sensors, as well as the voltages  $V_r$  and currents  $I_r$  of the reference sensor. The power required by a collector sensor and a reference sensor is  $P_c = V_c I_c$  and  $P_r = V_r I_r$  respectively. Since the heat losses of a reference sensor are mainly

**Figure 2.** Schematics of the IWTs that were used for the measurements: (a) Goodrich IWT of Collins Aerospace (image modified from Collins Aerospace, 2021), (b) Braunschweig Icing Wind Tunnel of the Technical University of Braunschweig (figure source: Institute of Fluid Mechanics of TU Braunschweig) and (c) Climatic Wind Tunnel of Rail Tec Arsenal (image modified from Rail Tec Arsenal, 2022).

**Table 1.** Specifications of the IWTs that were used for the measurements.

IWT	Test section size ( $L \times W \times H$ )	Temperature range	Airspeed
Collins IWT	$152 \times 56 \times 112 \text{ cm}^3$	$-30$ to $0 \text{ }^\circ\text{C}$	13 to $103 \text{ m s}^{-1}$
BIWT	$150 \times 50 \times 50 \text{ cm}^3$	$-20$ to $30 \text{ }^\circ\text{C}$	10 to $40 \text{ m s}^{-1}$
Rail Tec Arsenal	$90 \times 2.5 \times 3.5 \text{ m}^3$	$-30$ to $5 \text{ }^\circ\text{C}$	20 to $80 \text{ m s}^{-1}$

due to convection, its power consumption is assumed to be equal to (Korolev et al., 1998)

$$P_r = \alpha_r S_r (T_r - T_a). \quad (1)$$

Here,  $T_r$  and  $T_a$  are the temperatures of the reference sensor and the ambient air, and  $S_r$  is the sample area of the reference sensor. The factor  $\alpha_r$  is the heat transfer coefficient for the sensor, which in the literature is specified as  $\alpha_r = \kappa g_r Nu_r$ , where  $\kappa$  is the thermal conductivity of air,  $g_r$  the factor which takes into account the surface geometry of the sensor and  $Nu_r$  the Nusselt number (Korolev et al., 1998). In purely liquid clouds, the collector sensors need to heat the droplets from the droplet temperature  $T_d$  to the evaporation temperature  $T_e$ . The latent heat required for the evaporation at temperature  $T_e$  is  $L(T_e)$ .  $T_d$  can be assumed to be equal to  $T_a$ . Even a difference of  $10 \text{ }^\circ\text{C}$  between  $T_d$  and  $T_a$  would result in an error of less than 2% in the specific energy necessary for heating and evaporation ( $L^*$ ). This is because the latent heat

term  $L(T_e)$  is the dominant contribution to  $L^*$ :

$$L^* = c_w (T_e - T_a) + L(T_e). \quad (2)$$

Here,  $c_w = 4.1813 \text{ J g}^{-1} \text{ K}^{-1}$ , which is the specific heat capacity of water.  $L(T_e)$  can be approximated by the following formula (Science Engineering Associates, 2016):

$$L(T_e) = 2486.9696 - 2.025056 \cdot T_e - 29.288 \times 10^{-4} \cdot T_e^2 [\text{J g}^{-1}]. \quad (3)$$

The IWTs were unpressurized; hence  $T_e$  is equal to  $100 \text{ }^\circ\text{C}$ . Korolev et al. (1998) state a value of  $2580 \text{ J g}^{-1}$  as a good average for the value of  $L^*$ ; however this value was suggested for aircraft measurements where temperature and pressure differ from that in an IWT. Figure 3 shows that this value is indeed an underestimate for IWT conditions; hence  $L^*$  is determined from Eqs. (2) and (3) in this study.

The total power consumption of the collector sensors is calculated by adding the convective term to the power re-

quired for heating and evaporating the impinging water:

$$P_c = \alpha_c S_c (T_c - T_a) + \varepsilon W L^* S_c U. \quad (4)$$

Here,  $W$  denotes the water content of the air,  $S_c$  is the sensor sample area,  $U$  is the airspeed and  $\varepsilon$  is the collection efficiency of the sensor. A relation between the convective heat losses of the reference sensor and the convective heat losses of the collector sensor can be obtained from measurements in dry air:

$$\frac{P_{c,dry}}{P_r} = k. \quad (5)$$

The ratio  $k$  only depends on parameters such as airspeed, altitude and temperature (Korolev et al., 1998) and is thus constant for individual test points in IWTs. Rearranging and inserting Eq. (5) into Eq. (4), and solving for  $W$  yields

$$W = \frac{P_c - k P_r}{\varepsilon L^* S_c U}. \quad (6)$$

The collection efficiencies that are required for solving Eq. (6) are partly available from the literature. The shape of the LWC sensor is approximately cylindrical and its collision efficiency can be calculated analytically from the formulae of Finstad et al. (1988a) or Langmuir and Blodgett (1946); for this study we use the latter, which is also recommended by the AC-9C Aircraft Icing Technology Committee (2015) for the rotating cylinder method. It is worth noting that the computed efficiencies only take into account the collision efficiency of droplets with the sensor. The overall collection efficiency of the LWC sensor decreases once droplets reach sizes of 30–40  $\mu\text{m}$  due to droplet splashing, as has been shown in Schwarzenboeck et al. (2009). Collision efficiency curves of the 8 mm cone were published by Strapp et al. (2003) for velocities of 67 and 100  $\text{m s}^{-1}$  based on a 2D fluid simulation. We use the curve for the velocity value which best matches the actual tunnel velocity to correct the 8 mm cone measurements. Strapp et al. (2003) remark however that these collision efficiency curves may contain significant errors for small droplet sizes. Splashing is assumed to be irrelevant for the 8 mm cone in Appendix C conditions (Strapp et al., 2003). For the 12 mm cone, which is a new addition to the Nevzorov sensor head, no collision efficiencies have been published up to now. In this paper, we experimentally derive the collision efficiency of the 12 mm cone from the measurements that we obtained during the wind tunnel campaigns.

#### 4 IWT conditions and instrumentation

This section defines the IWT conditions that have been tested and the instruments, measurement principles, and uncertainties. We differentiate between three droplet spray categories: small droplet spray (SDS), freezing drizzle (FZDZ) and

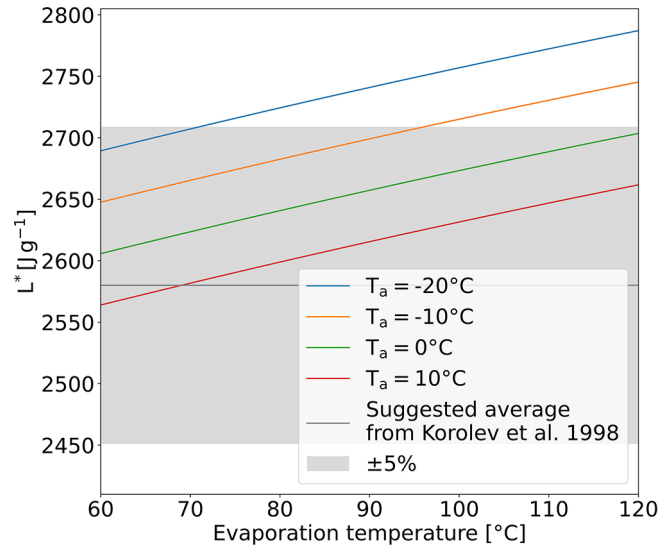

Figure 3. The energy needed to heat and evaporate water ( $L^*$ ) plotted versus the evaporation temperature  $T_e$ .

freezing rain (FZRA). SDS includes the nominal Appendix C conditions (Jeck, 2002), as well as conditions where the LWC and MVD are outside the Appendix C envelopes, but no supercooled large droplet mode ( $D > 100 \mu\text{m}$ ) is present. FZDZ and FZRA conditions include unimodal and bimodal SLD conditions, of which some fall within the LWC specifications of Appendix O (Cober and Isaac, 2012), while others exceed the maximum LWC significantly. The distinction between FZDZ and FZRA is made according to the maximum of the LWC distribution in the large droplet mode; if the maximum is positioned at a diameter smaller than 500  $\mu\text{m}$  we identify the condition as FZDZ, otherwise we identify it as FZRA. This definition is slightly different to that used in Cober and Isaac (2012), where FZRA is defined by the presence of droplets larger than 500  $\mu\text{m}$ . The distribution of the droplet spray produced in the wind tunnels is relatively broad so that sprays with a droplet mode centered around 200  $\mu\text{m}$  still contain a small, but not insignificant ( $> 1\%$  of total LWC) number of droplets larger than 500  $\mu\text{m}$ . We decided that such conditions are nonetheless better described by the characteristics of FZDZ as defined in Cober and Isaac (2012) and hence list them as such.

#### 4.1 Instrumentation

Complementary to the Nevzorov LWC measurements, LWCs of all the test points used in this work have been measured by the tunnel operators. These measurements are designated as the tunnel LWC and serve as a comparison to the Nevzorov measurements. For the tunnel LWC measurements, the IWT operators employed a wide range of instruments, which we refer to as the tunnel reference instrumentation. The tunnel reference instrumentation depends on the type of

the produced droplet spray. Collins and RTA use icing blades to measure SDS conditions. The LWCs for the SDS conditions of the BIWT were measured with high-accuracy flow meters, but the tunnel has previously also been calibrated with rotating cylinders and an isokinetic probe (IKP) (Knop et al., 2021). In FZDZ conditions the BIWT relies on flow meters again, while Collins uses a WCM-2000. RTA computes its LWC in FZDZ conditions from the measurements of multiple instruments, among them icing blades, the WCM-2000 (King-Steen et al., 2021b; Steen et al., 2016), the Nevzorov probe (Korolev et al., 1998), and the cloud, aerosol and precipitation spectrometer (CAPS) (Baumgardner et al., 2001, 2017). The LWC of FZRA conditions was determined solely from IKP measurements (Davison et al., 2012; Strapp et al., 2016; Ratvasky et al., 2021). An overview of all the instrumentation used in the tunnels is shown in Table 2.

Beside the LWC measurements, DSDs obtained with airborne instrumentation were provided by DLR, Embraer and the wind tunnel owners. The DSDs constitute an important input parameter for the collision efficiency calculation of the Nevzorov probe. At the BIWT we measured the DSDs with the DLR HALO CCP, which was flown during various flight campaigns (Voigt et al., 2017; Jurkat-Witschas et al., 2019; Voigt et al., 2022) and has been described in Braga et al. (2017a, b). The CCP used at Collins was provided by Embraer. For the measurements at RTA we use DSDs derived from data of a Fast Cloud Droplet Probe (FCDP) (Glienke and Mei, 2020; Kirschler et al., 2022), a Two-Dimensional Stereo Cloud Probe (2D-S) (Lawson et al., 2006), a Precipitation Imaging Probe (PIP) (Baumgardner et al., 2017), a CAPS that was provided by DLR and a Malvern Spraytec probe provided by the tunnel operator (Ferschitz et al., 2017).

#### 4.2 Measurements with the CCP

We now give an overview of the CCP and the data evaluation for the DSDs. The CCP consists of two instruments, the cloud droplet probe (CDP) which measures droplet size based on the intensity of the forward scattered light and the cloud imaging probe (CIP) which records the shadow images of droplets on its array of photo diodes. The CDP detects droplets in the size range 2–50  $\mu\text{m}$  and outputs data in bins with 1–2  $\mu\text{m}$  bin width. We applied a size binning for liquid droplets based on a laboratory calibration to the lower end of the CDP size range in order to consider ambiguities caused by the Mie resonances (Lance et al., 2010; Rosenberg et al., 2012).

The CIP measures particles in the size range 15–950  $\mu\text{m}$  with a size resolution of 15  $\mu\text{m}$ . We processed its data with the SODA software (Bansemmer, 2013). The software incorporates a shattering (Field et al., 2006) and a depth of field correction (Korolev, 2007). For the combination of the measurements of CDP and CIP we defined a threshold within the overlap region of the instruments at which we transitioned from using the CDP data to using the CIP data. The thresh-

old value was chosen in a way that ensured that the CDP provided sufficient sampling statistics. Depending on the number concentration of droplets in the transition region it therefore varied between 39 and 47  $\mu\text{m}$ . After combining the data of the two instruments we followed the procedure in Cober and Isaac (2012) and performed a logarithmic interpolation between the bin centers to obtain a size distribution with 1  $\mu\text{m}$  bins.

#### 4.3 Measurement uncertainties

All instruments are subject to measurement uncertainties, which we discuss now. For hot-wire LWC measurement techniques, Baumgardner et al. (2017) state a propagated uncertainty of 10%–30% due to errors related to the removal of convective heat losses and the uncertain response to large droplets and ice crystals. Only liquid water conditions were investigated in this study; hence uncertainties due to the response to ice crystals are irrelevant. We performed a detailed investigation of the error sources in the Nevzorov probe measurements (see Appendix A). The uncertainty values strongly depend on LWC, MVD, temperature, airspeed and the sensor that is considered. For the SDS measurements presented in this study, the uncertainties of the 8 mm cone and the 12 mm cone can be expected to be below  $\pm 11\%$  and  $\pm 15\%$  respectively once the MVD exceeds 20  $\mu\text{m}$ . Measurements of the LWC sensor are estimated to be accurate within  $\pm 15\%$  for MVDs between 10 and 20  $\mu\text{m}$ . We note that our uncertainties are in fairly good agreement with those stated in Korolev et al. (1998). For the WCM-2000, King-Steen et al. (2021a) found biases of 5%–15% between two sensor heads, which were caused by a misaligned calibration and an increased amount of solder on one of the sensing elements. For both instruments these accuracy values apply for the size range of typical Appendix C conditions, whereas uncertainties in SLD conditions are not yet quantified.

Uncertainties of accretion-based methods such as the rotating cylinder and the icing blade are generally assumed to be low in low LWC Appendix C conditions; Stallabrass (1978) states an absolute LWC accuracy within  $\pm 10\%$  for both methods in conditions with MVDs between 14 and 34  $\mu\text{m}$ . Accretion-based methods however have their limitations when high LWCs or large droplets are involved and uncertainties depend on the size of the element that is used (Steen et al., 2016; Orchard et al., 2019).

For optical particle measurements we distinguish between the sizing and the counting accuracy. For instruments based on light scattering, such as the CDP, the propagated uncertainty is 10%–50% for particle sizing, while the uncertainty in concentration is 10%–30% (Baumgardner et al., 2017). For imaging probes, uncertainties generally may extend from 10%–100% for both size and concentration (Baumgardner et al., 2017). For the CIP we performed an analysis of the uncertainty in the measured number concentration based on a laboratory calibration and information from the literature.

**Table 2.** Tunnel reference instrumentation used by the IWT operators.

IWT	LWC reference instrumentation			Droplet size reference instrumentation

According to the analysis, the uncertainty in the measured number concentration is smaller than 15 % for droplets larger than 80  $\mu\text{m}$  but could increase to 60 % for droplets smaller than 80  $\mu\text{m}$ .

Further uncertainty is introduced into the measurements due to the different mounting positions of the instruments. Differences in the mounting positions are especially problematic when the spray homogeneity is poor, as is often the case in SLD conditions (Ferschitz et al., 2017; Orchard et al., 2018). In this study, we generally attempted to measure at the same position with all our instruments. However, this was not always possible, either due to constraints from the wind tunnel or due to the inherent spatial separation of sensors on the same instrument. For example, on the CCP, the CDP and CIP sample volumes are separated by approximately 13.5 cm, and on the Nevzorov probe, the LWC sensor and the 12 mm cone are positioned approximately 2 cm above and below the 8 mm cone respectively. In the BIWT, we established from traverse measurements in bimodal conditions that the LWC in the area where the Nevzorov sensor head was placed was homogeneous within  $\pm 3\%$ . The CIP sample volume was positioned in the same area. The CDP was positioned outside of this area, but we assume that the small droplet spray that is measured by the CDP is evenly distributed across the wind tunnel cross section. At Collins, the Nevzorov probe was mounted horizontally in the wind tunnel, such that all its sensors measured at the same height. Collins provided information that the SDS and FZDZ conditions are uniform within  $\pm 10\%$  in the area spanned by the Nevzorov sensors. Due to mounting constraints in the wind tunnel, the measurement location of the Nevzorov was 45 cm downstream of the WCM-2000 calibration position. Assuming Stokes' law, the sedimentation of a 100  $\mu\text{m}$  diameter droplet over this distance is just 0.2 cm, but for a 400  $\mu\text{m}$  diameter droplet it is almost 3 cm. The sample position may therefore have had a minor influence on the measured LWC at Collins. For RTA, uniformity measurements presented in Breitfuß et al. (2019), as well as further internal tunnel calibrations, show that LWC deviations between the locations of the LWC sensor, the 8 mm cone and the 12 mm cone are no larger than  $\pm 5\%$  in FZDZ and FZRA conditions.

#### 4.4 IWT conditions

Figure 4 and Table 3 provide an overview of all the test points from the three IWTs used for this study. At Collins, we measured a total of 21 SDS conditions at airspeeds of 40, 67 and 85  $\text{m s}^{-1}$ . Eight different SDS conditions were measured in the BIWT at the maximum tunnel airspeed of 40  $\text{m s}^{-1}$ . At RTA, four SDS conditions were measured at a tunnel speed of 60  $\text{m s}^{-1}$ . The SDS conditions were selected in a way that large portions of the Appendix C icing envelopes were covered. Additional SDS test points at MVDs beyond 40  $\mu\text{m}$  were measured in order to characterize the collision efficiency of the Nevzorov probe at larger droplet sizes.

The FZDZ conditions vary significantly between the tunnels. The examined FZDZ test points represent the set of conditions which were attainable with the spray system of the tunnel and regarded as suitable under consideration of the trade-off between low LWC and preservation of icing cloud uniformity. Collins produced unimodal SLD conditions with MVDs between 128 and 221  $\mu\text{m}$  at an airspeed of 76  $\text{m s}^{-1}$ . At RTA and the BIWT we measured mostly bimodal freezing drizzle distributions with varying fractions of LWC in the small and large droplet modes. Only test point U19 at RTA is unimodal. Currently, of the three IWTs, only RTA is able to produce freezing rain conditions. We obtained measurements in unimodal and bimodal freezing rain conditions at airspeeds of 50 and 60  $\text{m s}^{-1}$  respectively.

#### 5 Derivation of collision efficiencies

The problem of droplet collision efficiency on various geometries has been thoroughly investigated in the literature (Langmuir and Blodgett, 1946; McComber and Touzot, 1981; Lozowski et al., 1983; Makkonen, 1984; Finstad et al., 1988a). A droplet trajectory can be described as a function of two parameters: the droplet inertia parameter  $K$ , which relates the droplet inertia to the drag forces that act on the droplet, and the free-stream droplet Reynolds number  $Re$  (Heinrich et al., 1991). The two parameters are specified in Eqs. (7) and (8) respectively.

$$K = \frac{1}{9} \frac{d^2 U \rho_w}{c \mu_a}, \quad (7)$$

**Table 3.** Overview of the test points measured in the SENS4ICE and ICE GENESIS IWTs. The LWC values stem from the internal tunnel calibration. MVD values were derived from CCP measurements at the BIWT and Collins and from CAPS and Malvern measurements at RTA. For bimodal distributions, the diameter corresponding to the maximum of the large droplet mode is provided in brackets behind the MVD.

<sup>b</sup> For testing purposes the tunnel temperature was raised above the melting point.

$$Re = \frac{\rho_a U d}{\mu_a} \quad (8)$$

In the equations  $d$  denotes the droplet diameter,  $U$  the free-stream velocity,  $\rho_a$  and  $\rho_w$  are the densities of air and water,  $c$  is the characteristic length of the geometry for which the impingement is calculated, and  $\mu_a$  is the dynamic viscosity of air. If the Reynolds number is held constant, droplet collision efficiencies increase with an increase in the droplet inertia parameter  $K$  (Heinrich et al., 1991). Therefore, larger droplets, a larger airspeed and a smaller sensor geometry re-

sult in higher collision efficiencies. Consequently, we expect lower collision efficiencies for the Nevzorov 12 mm cone than for the LWC sensor and the 8 mm cone.

One possibility to experimentally derive the collision efficiencies of the 12 mm cone is to compare its measurements in the IWT with a reference LWC value, measured with well-established sensors such as those listed in ARP5905 (AC-9C Aircraft Icing Technology Committee, 2015). Collision efficiency curves can then be estimated with a fit through the data points. Such reference LWC values exist for the SDS conditions of the three IWTs; however they were measured

**Figure 4.** IWT test points used in this study, grouped by droplet spray category. For unimodal test points, the markers represent the MVD, while for bimodal test points the diameter at the maximum of the large droplet mode is shown. We also show the Appendix C envelopes for continuous maximum icing conditions (CM) and intermittent maximum icing conditions (IM) and the Appendix O maximum LWC envelopes from Cober and Isaac (2012) for comparison.

with different instruments. Alternatively, the measurements of the Nevzorov LWC sensor and the 8 mm cone can be used as a reference. The collection efficiencies of these two sensors are well characterized; hence their measurements can be corrected and serve as a measure for the true tunnel LWC. The advantage of using these two sensors as a reference is that they were subjected to the exact same condition as the 12 mm cone; consequently the comparison is not affected by random fluctuations of LWC in the IWTs.

Since the collision efficiency curve changes with airspeed, we define three groups of measurements in Appendix C conditions, which can be seen in Fig. 6 and Table 4. Group 1 contains measurements at 40 m s<sup>-1</sup> from Collins and the BIWT, Group 2 contains measurements at 60 and 67 m s<sup>-1</sup> from Collins and RTA, and Group 3 contains measurements at 85 m s<sup>-1</sup> from Collins. The measurements in Group 2 differ in airspeed by 7 m s<sup>-1</sup>. We group these measurements together, because we assume that the gain in accuracy of the collision efficiency curve that we obtain from using more measurements outweighs the inaccuracy that we induce by not differentiating between the airspeeds.

We compute the LWC that was present in the tunnel from the LWC sensor and the 8 mm cone measurements of the Nevzorov. As mentioned before, large droplets tend to splash on the LWC sensor, whereas for the 8 mm cone the collision efficiency of small droplets is low, which makes the LWC estimate prone to large uncertainties. We use the appropriate sensor for each measurement; if the MVD is smaller than or equal to 20 μm we utilize the collision-efficiency corrected measurements of the cylindrical LWC sensor (LWC<sub>cyl</sub>), while for an MVD larger than 20 μm we use

**Table 4.** Number of small droplet spray measurements per airspeed group.

BIWT	8	0	0
Total	14	13	6

the collision-efficiency corrected 8 mm cone measurements (LWC<sub>8</sub>). From now on we call this combination of LWC values from the LWC sensor and the 8 mm cone the Nevzorov reference LWC and denote it as LWC<sub>Nevz</sub>. In an ideal experimental setup the Nevzorov probe would be exposed to monodisperse droplet distributions, the measurements of the 12 mm cone would be compared to LWC<sub>Nevz</sub> and a collision efficiency curve could be derived. Realistic conditions differ from that setup because dispersed droplet distributions are produced. In our experiments, these droplet distributions are derived from the CCP or from the tunnel reference instrumentation. We assume the collision efficiency curve of the 12 mm cone can be described by a function  $f(d)$ , where  $d$  is the droplet diameter. For an ideal measurement, the raw LWC measured by the 12 mm cone ( $W_{12}$ ) is equal to the LWC in the tunnel, which we approximate with LWC<sub>Nevz</sub>, multiplied by the overall collision efficiency of the 12 mm cone ( $\epsilon_{12}$ ); see Eq. (9).

$$W_{12} = \epsilon_{12} \cdot LWC_{Nevz} = \sum_{d_{min}}^{d_{max}} f(d_i) \cdot v(d_i) \cdot LWC_{Nevz} \quad (9)$$

Here,  $v(d_i)$  is the fraction of total LWC in size bin  $i$ , calculated from the available size distributions. The question arises of what kind of analytical function  $f(d)$  should be. Korolev et al. (1998) suggested Eq. (10) for  $f(d)$ , where  $D_0$  is the free parameter, which can be adjusted depending on the sensor that is modeled. We also experimented with other functional forms but found that Korolev’s curve produced the best results.

$$f(d) = \frac{d^2}{(D_0^2 + d^2)} \quad (10)$$

In the next step we formulate a system of equations for each airspeed group, where each equation represents one measurement and is of the form of Eq. (9). We find the optimal solution for  $D_0$  for each airspeed group with least squares estimation, which minimizes the sum of squared residuals (RSS; see Eq. 11) with respect to  $D_0$ .

$$RSS = \sum_{j=1}^n \left( \frac{W_{12, TP_j}}{LWC_{Nevz, TP_j}} - \sum_{d_{min}}^{d_{max}} f(d_i, D_0) \cdot v_{TP_j}(d_i) \right)^2 \quad (11)$$

**Table 5.**  $D_0$  values computed from the curve fit for the different airspeed groups. The uncertainties represent the  $1\sigma$  intervals that are associated with the curve fit.

Group	G1	G2	G3
$D_0$	$18.3 \pm 1.1$	$18.7 \pm 0.6$	$17.6 \pm 1.3$

In the equation above,  $TP_j$  denote the individual test points. The results of the least squares estimation is shown in Table 5. Figure 5 shows the computed collision efficiency curves. The three curves for the three different airspeed groups lie very close together so that they are hardly distinguishable. The collision efficiency of a  $10\mu\text{m}$  diameter droplet is only 0.2 but then rises steeply to 0.5 for  $20\mu\text{m}$  droplets. Beyond  $20\mu\text{m}$  the slope of the collision efficiency curve decreases continuously and the collision efficiency attains 0.7 for  $30\mu\text{m}$  droplets and 0.9 for  $60\mu\text{m}$  droplets. We note that the collision efficiency curve for Group 1 ( $40\text{ m s}^{-1}$ ) is slightly higher than that of Group 2 ( $60$  to  $67\text{ m s}^{-1}$ ). This is unexpected, because a higher airspeed leads to higher momentum and therefore results in a higher collision efficiency, in line with Eqs. (7) and (8). However, within the stated error margins the scenario  $D_{0,G1} < D_{0,G2}$  is also possible. Figure 6 shows the corrected LWC measurements from the 12 mm cone ( $\text{LWC}_{12}$ ) and  $\text{LWC}_{\text{Nevz}}$  for the SDS test points. For all measurements the collision efficiency was computed using the full DSD. Each row of Fig. 6 contains a different airspeed group. The left panels depict the ratio of  $\text{LWC}_{\text{Nevz}}$  to the tunnel LWC; i.e., they compare how well the reference measurements from the Nevzorov probe and the tunnel agree. The shaded areas denote 10% and 20% deviation from the tunnel LWC measurements. The comparisons show a good agreement between  $\text{LWC}_{\text{Nevz}}$  and the tunnel LWC, where, across all airspeed groups, 58% and 94% of the Nevzorov measurements fall within  $\pm 10\%$  and  $\pm 20\%$  of the tunnel LWC respectively. The scatter of the data points can therefore be explained through the combined uncertainties of the Nevzorov probe and the wind tunnel.

The right panels show the ratio of  $\text{LWC}_{12}$  to the tunnel LWC. For airspeed Group 2 (Fig. 6d),  $\text{LWC}_{12}$  exhibits a similarly good agreement to the tunnel LWC as  $\text{LWC}_{\text{Nevz}}$  (Fig. 6c). For airspeed Groups 1 and 3 (Fig. 6b and f), the discrepancies between  $\text{LWC}_{12}$  and the tunnel LWC are a bit larger than between  $\text{LWC}_{\text{Nevz}}$  and the tunnel LWC (Fig. 6a and e). Across all airspeed groups, 42% and 79% of the  $\text{LWC}_{12}$  values fall within  $\pm 10\%$  and  $\pm 20\%$  of the tunnel LWC respectively. The outliers at low MVDs are mostly data points with high LWCs. There has been an ongoing discussion concerning the ability of the Nevzorov to evaporate all of the impinging water. For an earlier, shallower version of the 8 mm TWC cone, Emery et al. (2004) observed that a pool of water formed inside the cone and was occasionally swept out, which led to an underestimate of the LWC. The ef-

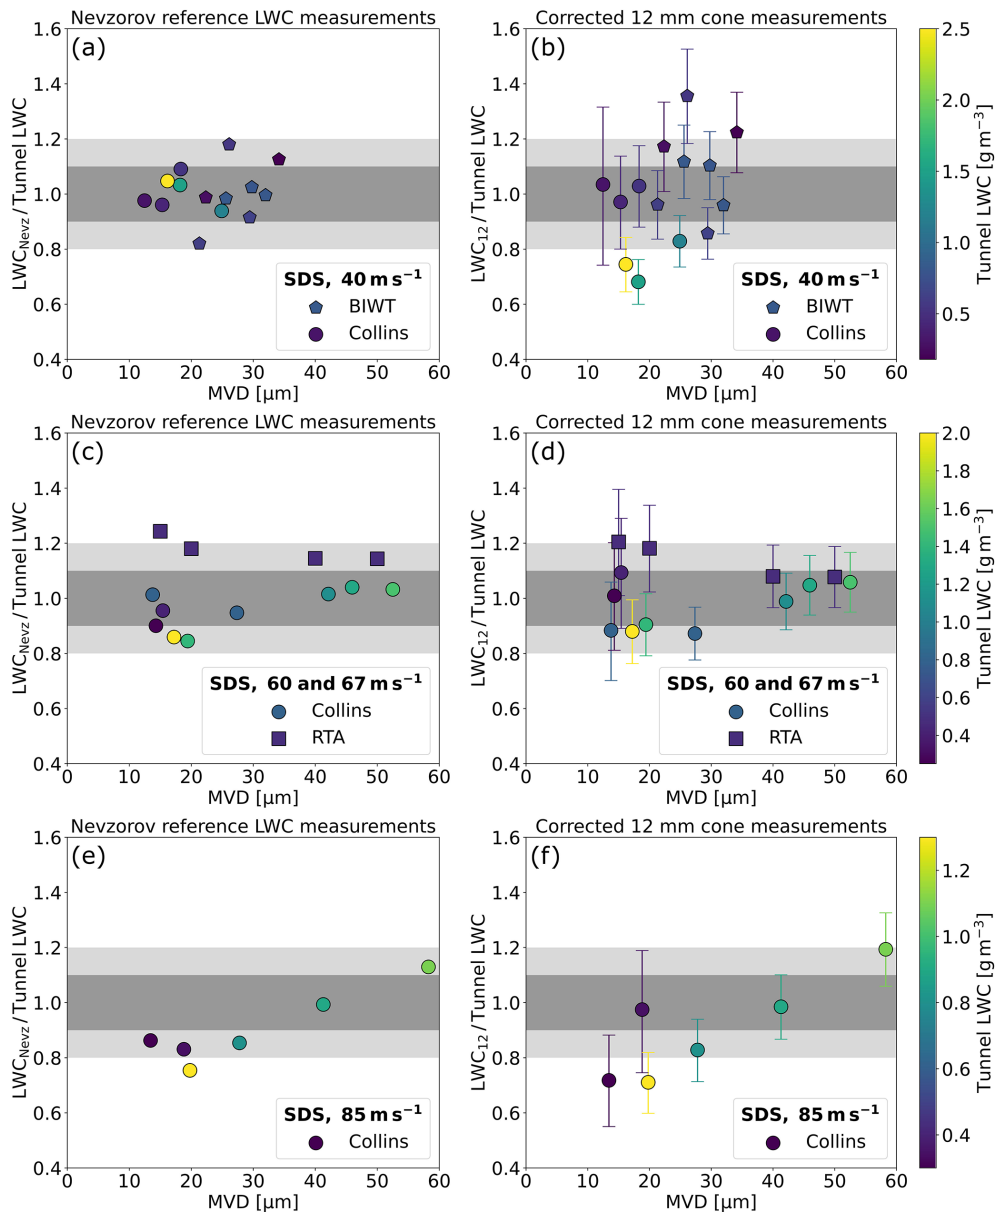

**Figure 5.** Collision efficiency curves of the 12 mm cone for the three airspeed groups; the collision efficiencies of the LWC sensor and the 8 mm cone from the literature are shown for comparison.

fect occurred during ice shaver conditions run at an airspeed of  $67\text{ m s}^{-1}$  and a TWC larger than  $2.1\text{ g m}^{-3}$ . For this work, a thorough analysis of the data found no evidence of pooling. Pooling and subsequent underestimates of LWC should be a function of LWC flux. While  $\text{LWC}_{12}$  is lower than the tunnel LWC for some of the high LWC flux test points, it is equal or higher for many others (see Fig. 6 and Table 3). The discrepancy between  $\text{LWC}_{12}$  and the tunnel LWC for the low MVD and high LWC points can in part be explained through droplet coincidence effects in the CDP. The number concentrations for these test points exceeded  $2000\text{ cm}^{-3}$ , and droplet coincidence (Lance et al., 2010; Lance, 2012) was present (see Appendix B). Droplet coincidence results in a shift towards larger particles in the size distribution, which in turn decreases the applied collision efficiency. The magnitude of the effect and its exact influence on  $\text{LWC}_{12}$  could not be determined, because the interarrival time data, which we use to correct for coincidence, were not available for the measurements at Collins.

## 6 Nevzorov probe measurements in unimodal SLD conditions

The Nevzorov probe was also tested in unimodal large droplet conditions; see Table 3. These test points provide valuable information on the response of the Nevzorov sensors to large drops. Figure 7 shows the results of the measurements in comparison to the tunnel LWC, determined with the WCM-2000 instrument for the FZDZ cases (except for the lowest MVD FZDZ test point that was measured at RTA with multiple instruments) and with an IKP for the FZRA test points. No collision efficiency corrections were applied to any of these measurements, because the droplet diameters were deemed to be sufficiently large for collision efficiency effects to be irrelevant (hence  $\text{LWC}_{12} = W_{12}$ ). The overall

**Figure 6.** Comparison of the Nevzorov reference LWC and the corrected 12 mm cone LWC to the tunnel LWC for the three different airspeed groups. The error bars incorporate all uncertainty sources of the Nevzorov probe as detailed in Appendix A, including the uncertainty in the collision efficiency curve that is described by the standard deviation of  $D_0$  (see Table 5). The error bars do not consider uncertainties not related to the Nevzorov probe, e.g., the IWT variability.

agreement between the Nevzorov and the tunnel LWC is good; all  $LWC_8$  measurements and all but one  $LWC_{12}$  measurement fall within  $\pm 20\%$  of the tunnel LWC.  $LWC_8$  and  $LWC_{12}$  generally follow a similar trend in comparison to the tunnel LWC, but the  $LWC_{12}$  measurement is on average 6.5% higher than the  $LWC_8$  measurement. For the FZDZ test points, where the tunnel LWC was determined with the WCM-2000,  $LWC_8$  and  $LWC_{12}$  increasingly exceed the tunnel LWC for increasing MVD values. This does not apply for

the FZRA test points, for which the tunnel LWC was determined with the IKP.

The results suggest that the Nevzorov TWC sensors are better suited than the WCM-2000 for the collection of droplets with diameters of approximately  $200\ \mu\text{m}$  or more. A possible explanation is the greater depth and width of the Nevzorov sensors, which allows them to retain most of the large droplets. Splashing and bouncing effects, similar to those described by Korolev et al. (2013) for an earlier, shallower version of the Nevzorov TWC cone, might occur

**Figure 7.** Measurements of the 12 mm cone and the 8 mm cone in comparison to the tunnel LWC in unimodal SLD conditions. The tunnel LWC is based on WCM-2000 measurements for all the FZDZ test points and on the IKP for the FZRA test points.

on the 2.1 mm wide WCM-2000 TWC sensor. In line with these observations, a comparison of the WCM-2000 and the IKP shows that the LWC measurements of the IKP exceeded those of the WCM-2000 (Lang et al., 2021) in FZRA conditions even by as much as 65 %.

We remark that there can be other factors which cause or contribute to the discrepancies between Nevzorov and WCM-2000, such as the different mounting positions of the two instruments or an uneven distribution of the large droplet spray. Also, the high LWC large droplet spray at Collins led to oscillations of the sensor head, which may have affected the result of the measurements.

The fact that LWC<sub>12</sub> is on average higher than LWC<sub>8</sub> suggests that the 12 mm cone is preferable to the 8 mm cone for the collection of large droplets; as its depth is larger and its perimeter-to-area ratio is smaller than that of the 8 mm cone, the probability of droplet re-entrainment into the airflow after impacting inside the cone is reduced. However, we note that the difference between the two cones is still within the uncertainty range of the instrument.

## 7 Application of collision efficiencies in bimodal SLD conditions

We now apply the newly computed droplet collision efficiencies to bimodal distributions measured in the BIWT and the RTA wind tunnel. As Collins only produces unimodal DSDs, there are no data available from this IWT. An overview of cumulative liquid water content (CWC) from the bimodal DSDs measured with the CCP in the BIWT can be seen in Fig. 8. Often, collision efficiencies of DSDs are approximated by using the MVD as a representative diameter for the entire distribution. This has been shown to work well for

small cylindrical sensors and unimodal droplet distributions (Stallabrass, 1978; Finstad et al., 1988b). Recently, Sokolov and Virk (2019) found that Langmuir A–J distributions with similar MVDs had very different collision efficiencies on a 30 mm cylinder at an airspeed of 4 m s<sup>-1</sup>. Furthermore, larger errors can be introduced when using the MVD approximation for bimodal distributions (FAA, 2014). Van Zante et al. (2021) also caution that bimodal distributions cannot be fully captured and represented by the MVD. We investigate the magnitude of the errors introduced by using the MVD approximation for droplet collision efficiency for a number of bimodal distributions measured in the BIWT; see Fig. 8. The figure also shows the relative error in the LWC when the MVD approximation for droplet collision efficiency is used. It highlights the importance of computing the collision efficiency from the entire DSD, especially for sensors such as the 12 mm cone where a large collision efficiency correction is applied. In one bimodal distribution the error from the usage of the MVD approximation for droplet collision efficiency exceeded 30 %. Note that the relative error is not a function of the MVD but rather depends on how well the MVD represents the DSD. As a consequence of the findings presented above, we use the full DSD as input to the collision efficiency function when computing LWC<sub>12</sub> and LWC<sub>8</sub> in bimodal distributions.

In Fig. 9 and Table 6 we present a comparison of LWC<sub>12</sub> to the tunnel LWC for the bimodal FZDZ and FZRA conditions that we measured in the BIWT and at RTA. The LWC<sub>8</sub> is plotted for comparison. The results show that LWC<sub>12</sub> and LWC<sub>8</sub> agree within  $\pm 20\%$  with the tunnel LWC for all but one test point. We also observe that the measurements of the two Nevzorov cones, LWC<sub>12</sub> and LWC<sub>8</sub>, coincide closely with each other once the MVD exceeds 24 μm. At lower MVDs, LWC<sub>12</sub> and LWC<sub>8</sub> diverge into opposite directions from the tunnel LWC.

The results prove that reliable measurements of LWC in bimodal SLD conditions can be achieved with the 12 mm TWC cone of the Nevzorov probe. The collision efficiency correction appears to be very accurate once the MVD exceeds 24 μm. The divergence of LWC<sub>12</sub> and LWC<sub>8</sub> from the tunnel LWC at lower MVD can be seen as an indication that minor errors still exist in the collision efficiency curve of the 12 mm cone and possibly also in that of the 8 mm cone, as acknowledged by Strapp et al. (2003). The analytical form for the collision efficiency curve of the 12 mm cone is simple; therefore it is probable that the curve cannot accurately represent the collision efficiency for all diameters. Furthermore, the collision efficiency at small diameters is low so that even a small offset in the curve introduces large errors in the result. For the test point at an MVD of 61 μm, both LWC<sub>12</sub> and LWC<sub>8</sub> exceed the tunnel LWC by approximately the same value, and the offset is consistent for both measurements that were made in this condition. This indicates that the discrepancy is not due to a problem with the Nevzorov probe or the collision efficiency correction, but more likely

**Figure 8.** (a) Cumulative liquid water content of the bimodal DSDs measured in the BIWT. The distributions with the MVDs of 16, 18 and 61  $\mu\text{m}$  have a small droplet mode centered around 15  $\mu\text{m}$  and a large droplet mode at approximately 230  $\mu\text{m}$ . They differ mainly in the ratio of LWC contained in small droplets to LWC contained in large droplets. The distributions with MVDs of 24 and 34  $\mu\text{m}$  have their small droplet mode centered at 20 and 30  $\mu\text{m}$  respectively and their large droplet mode at 166  $\mu\text{m}$ . (b) Relative error of the LWC estimate that is introduced when approximating the collision efficiency from the MVD as compared to the collision efficiency estimated using the DSDs shown on the left side.

**Figure 9.** Same as Fig. 7 but for bimodal distributions and with collision efficiencies applied. For the BIWT FZDZ test points, the tunnel LWC is based on flow meter measurements. The tunnel LWC of the FZDZ test points from RTA was determined from a combination of icing blade and WCM-2000. The tunnel LWC of the FZRA test points from RTA stems from a combination of icing blade and IKP measurements. Table 6 lists the IWT where the individual test points originated.

a larger uncertainty in the tunnel calibration exists for this point. Finally we would like to note that errors in the size distribution, which we use as an input for the computation of the collision efficiency, propagate into the errors of the LWC.

### 8 Conclusions

This work investigates the performance of a new, 12 mm diameter TWC cone of the Nevzorov probe, using data col-

lected in three different IWTs. We compared the LWC measured with the 12 mm cone to the measurements of the LWC sensor and the 8 mm cone of the Nevzorov probe as well as to the tunnel LWC. We found that a large correction needs to be applied to compensate for the low droplet collision efficiency of the cone. We experimentally derived this collision efficiency for three different airspeeds, using test points with MVDs between 12 and 58  $\mu\text{m}$ . For the shape of the collision efficiency curve we prescribed the functional form suggested in Korolev et al. (1998). In order to obtain the highest accuracy, we used the droplet size distributions of each individual test point for the derivation. We verified the capability of the 12 mm cone to collect SLDs through a comparison with the tunnel reference instrumentation, which included a WCM-2000 and an IKP. The results indicate that the 12 mm cone has better droplet collection properties than the WCM-2000 when the droplet size exceeds 200  $\mu\text{m}$ . Even in FZRA conditions, the 12 mm cone does not suffer from any significant losses of LWC; instead our comparison showed a good agreement to the values of the IKP. The 12 mm cone also appears to be better suited for the collection of SLDs than the 8 mm cone, because it measured slightly but consistently higher LWC values. The difference between the two cones is however still within their mutual uncertainty range.

We subsequently applied the new collision efficiency correction to measurements collected with the 12 mm cone in bimodal distributions and compared the resulting LWCs to those of the 8 mm cone and the tunnel LWC. The comparison showed an agreement within  $\pm 20\%$  with the tunnel LWC for all but one test point, highlighting the ability of the 12 mm cone to provide accurate measurements across the entire size range of Appendix O conditions. We observed that some inaccuracies remain in the computed curves at small droplet

**Table 6.** Comparison of the  $LWC_{12}$  to the tunnel LWC and  $LWC_8$ . The values of test points that were measured multiple times were averaged.

Test point	Tunnel	MVD [ $\mu\text{m}$ ]	$LWC_8/\text{tunnel LWC}$	$LWC_{12}/\text{tunnel LWC}$	$\varepsilon_{12\text{ mm}}$
522	BIWT	16	0.94	1.07	0.49
521	BIWT	18	0.93	1.16	0.53
524	BIWT	24	1.02	1.06	0.61
U13	RTA	24	1.10	1.10	0.66
525	BIWT	34	1.06	1.07	0.72
537	BIWT	61	1.25	1.21	0.70
U15	RTA	102	0.91	0.89	0.85
U18	RTA	102	0.98	0.95	0.84
TP7	RTA	534	1.02	0.95	0.90
TP8	RTA	534	1.02	0.91	0.90

diameters and caution should therefore be exercised when using the 12 mm cone in conditions that contain strong small droplet modes. For such conditions the collision efficiency curve for the 12 mm cone may be applied, but the corrected LWC readings should be compared to those of the LWC sensor and the 8 mm cone to assess their plausibility.

We also investigated the magnitude of the errors that can be introduced when one approximates the collision efficiency via the MVD instead of using the entire size distribution. The error depends on the collision efficiency correction that is applied and the size distribution. For the collision efficiency curve of the 12 mm cone the error exceeded 30 % in one case, which stresses the importance of using the entire size distribution in the collision efficiency calculation.

In summary, our results and findings demonstrate that the 12 mm cone of the Nevzorov probe is suitable for the measurement of SLD icing environments. Future IWT and flight campaigns with the Nevzorov will be able to use the 12 mm cone as a reliable source for the LWC with excellent properties for the collection of SLDs. The larger sample area of the 12 mm cone also represents an improvement over the 8 mm cone, which is especially relevant when measuring FZDZ, FZRA or mixed-phase conditions in natural clouds, where very few large particles are present, and a short sampling time is crucial.

#### Appendix A: Uncertainties of the Nevzorov probe measurements

Like any other measurement method, the Nevzorov probe measurements are subject to uncertainties. Here, we will attempt to quantify the uncertainties. First of all, let us categorize the uncertainties which affect the Nevzorov measurements:

- *general accuracy.* This category comprises all the uncertainties which are intrinsically connected to the sensor, e.g., uncertainties related to the response of the electronics or slight differences in the sensor geometry.

Each Nevzorov sensor head is handmade; therefore we consider it likely that some differences exist between each of them. We conservatively estimate these uncertainties to influence the LWC measurement by up to  $\pm 10\%$ .

- *accuracy of the convective heat loss term.* The convective heat losses that are experienced by each sensor depend on airspeed, temperature, pressure and the sensor geometry. We will disregard the influence of pressure changes here, as it was approximately constant in all wind tunnels. Generally, a higher airspeed, lower temperature and larger sensor geometry lead to larger convective heat losses. However, in order to assess how an inaccuracy in the estimated convective heat losses affects the overall LWC measurement, we need to consider the contribution of the convective heat-loss term to the total power expenditure. The contribution of the convective heat-loss term decreases with increasing LWC; hence the relative error caused by an inaccuracy in the estimated convective heat losses is smaller for high LWC test points than for low LWC test points. To ensure comparability, we state all uncertainties with respect to a reference LWC value of  $0.2\text{ g m}^{-3}$ . The 8 mm cone and the 12 mm cone have larger absolute convective heat losses than the LWC sensor; however they also capture significantly more liquid water due to their larger sample area. Their inverted-conical shape inhibits the airflow and thus reduces convective heat losses (see Fig. A1). The energy that is expended by the 8 and 12 mm cone for convective heating per unit volume of air is 2.5 to 3 times less than that of the LWC sensor. Lastly, convective heat losses increase sub-linearly with airspeed, while the liquid water influx on the sensor sample area is a linear function of airspeed. Consequently, measurements at high airspeed are less affected by errors in the convective heat loss term. For the wind tunnel test points, we were able to determine the factor  $k$  with an uncertainty below 2 %. The error

that results from this uncertainty can amount to approximately 11 % for the LWC sensor under the least favorable conditions ( $T_a = -20^\circ\text{C}$ ,  $U = 40\text{ m s}^{-1}$ ). For the 8 and 12 mm cone the uncertainties for this condition are 5 % and 3.5 % respectively. In favorable conditions, such as  $T_a = -10^\circ\text{C}$  and  $U = 85\text{ m s}^{-1}$ , the uncertainties due to convective heat losses for the LWC, 8 mm cone and 12 mm cone sensors are only 7 %, 2.5 % and 2 % respectively.

– *accuracy of the collision efficiency.* The formulations of Langmuir and Blodgett (1946) and Finstad et al. (1988a) for the flow of droplets around a cylinder agree within 2 % for the droplet sizes that are relevant for this study. Hence we assume that the uncertainty in the LWC collision efficiency estimate is not greater than that value. Strapp et al. (2003) did not publish any uncertainties for their collision efficiency curve of the 8 mm cone but noted that the curve may contain significant errors at small droplet diameters. We found that the values of  $\text{LWC}_8$  indeed fall significantly below that of the tunnel LWC and  $\text{LWC}_{\text{cyl}}$  at small droplet diameters (see Fig. A2). A downward shift of the collision efficiency curve by 0.14 and 0.07 yielded the best agreement of  $\text{LWC}_8$  with the tunnel LWC and  $\text{LWC}_{\text{cyl}}$  respectively if only test points with an MVD < 20  $\mu\text{m}$  were considered. Above 20  $\mu\text{m}$  the agreement between  $\text{LWC}_8$  and the tunnel LWC is very good; only a very slight downward shift of the collision efficiency curve by 0.02 would lead to marginally lower residuals between the tunnel LWC and  $\text{LWC}_8$  (we did not compare  $\text{LWC}_8$  to  $\text{LWC}_{\text{cyl}}$ , because we considered the measurement of the LWC sensor unreliable because of possible splashing effects). We therefore assume that the collision efficiency curve of Strapp et al. (2003) is accurate to within  $\pm 0.02$  for diameters of 20  $\mu\text{m}$  or larger.

We consider all the abovementioned uncertainties to be uncorrelated biases which are Gaussian distributed. We combine them using the procedure suggested in AGARD-AR-304 (1994). For  $\text{LWC}_{\text{cyl}}$  the maximum combined uncertainty that we expect for MVDs between 10 and 20  $\mu\text{m}$  is  $\pm 15\%$ ; in IWT conditions which are more favorable in terms of the magnitude of the convective heat losses, the uncertainty decreases to approximately  $\pm 12\%$ . For  $\text{LWC}_8$  the maximum uncertainty in the MVD range from 20 to 60  $\mu\text{m}$  is  $\pm 11\%$ . The uncertainty in  $\text{LWC}_{12}$  at small MVDs is inevitably large and reaches up to  $\pm 29\%$  at an MVD of 12  $\mu\text{m}$  and  $U = 40\text{ m s}^{-1}$ . However, the uncertainty rapidly decreases to  $\pm 19\%$  at an MVD of 15  $\mu\text{m}$  and to  $\pm 14\%$  at an MVD of 22  $\mu\text{m}$ . Uncertainties in the convective heat losses of the 12 mm cone are small compared with the other uncertainty sources; therefore changes in airspeed or temperature should only cause minor differences in the stated uncertainties.

**Figure A1.** Convective heat losses of the Nevzorov sensors per volume of air. The volume of air that a sensor is exposed to is computed from the sample area and the airspeed. Turbulence and blockage effects that may occur around the sensors are not considered for this plot.

In SLD conditions, further measurement uncertainties are introduced due to the possibility of droplet splashing. However, the Nevzorov sensors were designed to mitigate splashing effects. On the basis of high-speed camera images, Korablev et al. (2013) claim that the number of ice particles that bounce from the 8 mm cone is small. The design of the new 12 mm cone is even better than that of the 8 mm cone for retaining ice particles and droplets. This suggests that the influence of droplet splashing effects is rather small, but at this point we cannot quantify the exact magnitude. A second source of uncertainty in SLD conditions is caused by high-frequency flutter of the sensor head around its axis of rotation, which was observed to be significantly stronger during SLD conditions with high LWC than in SDS conditions. This flutter led to (very short-term) deflections of the sensor head of up to  $\pm 20^\circ$ . The change in the sample area caused by the flutter is however just a few percent. We note that the previously mentioned uncertainty sources, which affect the Nevzorov probe in general, are not increased in SLD conditions compared to SDS conditions. In fact, the uncertainty of the collision efficiency in SLD conditions is very close to zero, because the collision efficiency of SLDs is essentially 100 %.

## Appendix B: Droplet coincidence in the CDP measurements

Section 5 mentions that droplet coincidence in the CDP is present for some of the high LWC test points. Droplet coincidence occurs when two or more droplets are measured by the instrument at the same time (Baumgardner et al., 1985). These coincident droplets are counted as a single and often larger droplet. Coincidence can be detected through an anal-

**Figure A2.** Comparison of the collision-efficiency corrected 8 mm cone measurements to the tunnel LWC (a) and to the collision-efficiency corrected LWC sensor measurements (b).

**Figure B1.** Average path length while sizer above threshold plotted against the number concentration for the SDS test points measured at Collins. The average path length is a measure similar to the average transit time but multiplied with the airspeed in order to make test points with different airspeeds comparable.

ysis of particle transit times, which increase if coincidence is present (Lance, 2012). Figure B1 shows the average path length during which the CDP sizer was above the detection threshold, plotted versus the number concentration. The average path length is the average transit time multiplied with the airspeed. This was done in order to compare test points with different airspeeds. Test points with larger MVDs produce longer average path lengths, which is to be expected simply due to the larger particle size. However, Fig. B1 shows that longer average path lengths are also observed for test points with high number concentrations. Since we know that coincident droplets cause longer transit times, we deduce that coincidence occurred for these test points.

**Data availability.** The complete data sets from the BIWT and RTA are available at <https://doi.org/10.5281/zenodo.6817112> (Lucke et al., 2022). Collins IWT considers raw measurements from its tun-

nel as confidential information; therefore the data cannot be made public.

**Author contributions.** JL prepared the manuscript, operated the DLR probes at Collins and in the BIWT and was responsible for the overall data analysis. TJW assisted in developing the concept for the manuscript, the discussion of the data evaluation, and the planning and execution of the IWT campaigns. MH, WB and VRB conducted the measurements at Collins, RTA and the BIWT respectively and provided the wind tunnel data. RH and VH operated the DLR probes during the measurements at RTA. MM assisted with the analysis of the CIP data. TJW and CV designed the experiment. All authors commented on the manuscript.

**Competing interests.** The contact author has declared that none of the authors has any competing interests.

**Disclaimer.** Publisher's note: Copernicus Publications remains neutral with regard to jurisdictional claims in published maps and institutional affiliations.

**Acknowledgements.** We thank Galdemir Botura and the technical staff at Collins Aerospace for supporting icing innovation and for the constructive and inspiring collaboration within the SENS4ICE project. We thank Embraer for providing their Cloud Combination Probe and Matt Freer for his support in the measurement campaign at the Collins IWT. We also appreciate the help and expertise of Stephan Sattler during the wind tunnel measurements at the BIWT and the support of Inken Knop in the data evaluation. We furthermore thank Alexei Korolev and one anonymous reviewer for their helpful and constructive reviews.

**Financial support.** This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement no. 824253 (SENS4ICE). This project has received funding from the European Union's Horizon

2020 research and innovation programme under grant agreement no. 824310 (ICE GENESIS). Furthermore, research performed as part of this work has received funding from the German Research Foundation (DFG, Deutsche Forschungsgemeinschaft) under the Priority Program SPP PROM Vo1504/5-1.
