**Highlights (for review)**

[Click here to download Highlights \(for review\): highlights distribution shear stress 2015-05-11.docx](#)

- The principle of Levels of Approximation from the *fib* Model Code is applied to assessment, resulting in Levels of Assessment.
- This paper focuses on Level of Assessment II for reinforced concrete slab bridges, for which the shear stress distribution at the support is studied.
- An experiment is compared with a finite element model to come up with a recommendation for the distribution of the peak shear stress in finite element models.
- The recommended width for the distribution is 4 times the effective depth to the longitudinal reinforcement.
- A case study has been made to compare the results of Level of Assessment I and II, and the increased accuracy and reduced conservatism for the higher Level of Assessment is confirmed.

Existing reinforced concrete solid slab bridges in the Netherlands are re-assessed for shear based on a Unity Check: the ratio of the shear stress caused by the applied loads to the shear capacity of the concrete cross-section. The governing shear stress resulting from the self-weight, weight of the wearing surface, distributed and concentrated live loads can be determined with a simplified spreadsheet-based method, the Quick Scan (Level of Assessment I) as well as with a linear finite element model (Level of Assessment II). When a finite element model is used, a distribution of shear stress over the width of the slab bridge is automatically found. To compare the governing shear stress caused by the loads to the shear capacity, it is necessary to determine over which length the peak shear stress from the finite element model can be distributed. To answer this question, a finite element model is compared to an experiment. The experiment consists of a continuous, reinforced concrete slab subjected to a single concentrated load close to the support. Seven bearings equipped with load cells that measure the reaction force profile along the width of the slab are used to compare to the stress profile obtained from the finite element model. From this analysis, it is found that the peak shear stress in a linear finite element model can be distributed over  $4d_l$  with  $d_l$  the effective depth to the longitudinal reinforcement of the slab. The comparison of measured reaction force profiles over the support to the stress profile from a finite element model results in a research-based distribution width that replaces the rules of thumb that were used until now.

## 1 **Abstract**

2 Existing reinforced concrete solid slab bridges in the Netherlands are re-assessed for shear  
3 based on a Unity Check: the ratio of the shear stress caused by the applied loads to the shear  
4 capacity of the concrete cross-section. The governing shear stress resulting from the self-  
5 weight, weight of the wearing surface, distributed and concentrated live loads, can be  
6 determined with a simplified spreadsheet-based method, the Quick Scan (Level of  
7 Assessment I) as well as with a linear finite element model (Level of Assessment II). When a  
8 finite element model is used, a distribution of shear stresses over the width of the slab bridge  
9 is automatically found. To compare the governing shear stress caused by the loads to the  
10 shear capacity, it is necessary to determine over which width the peak shear stress from the  
11 finite element model can be distributed. To answer this question, a finite element model is  
12 compared to an experiment. The experiment consists of a continuous, reinforced concrete  
13 slab subjected to a single concentrated load close to the support. Seven bearings equipped  
14 with load cells that measure the reaction force profile along the width of the slab are used to  
15 compare to the stress profile obtained from the finite element model. From this analysis, it is  
16 found that the peak shear stress in a linear finite element model can be distributed over  $4d_l$   
17 with  $d_l$  the effective depth to the longitudinal reinforcement of the slab. The comparison of  
18 measured reaction force profiles over the support to the stress profile from a finite element  
19 model results in a research-based distribution width that replaces the rules of thumb that were  
20 used until now.

## 1 **1. Introduction**

2 The Dutch road network underwent a large expansion during the decades following the  
3 Second World War. Fifty percent of the bridges and viaducts in the Netherlands were built  
4 before 1976. The bridges that were constructed at that time are now reaching the end of their  
5 originally devised service life. Since the original design and construction of these bridges, the  
6 traffic loads and volumes have increased significantly, resulting in heavier live load models  
7 in NEN-EN 1991-2:2003 [1]. At the same time, the shear provisions of the recently  
8 introduced Eurocode NEN-EN 1992-1-1:2005 [2] allow for smaller shear capacities of  
9 concrete cross-sections than the former national Dutch code NEN 3880:1974 [3] and NEN  
10 1009:1962 [4] (or earlier).

11 One bridge type that, upon assessment, is particularly vulnerable to these code changes is  
12 the subset of the reinforced concrete solid slab bridges. This bridge type is common in the  
13 older part of the Dutch road network, and is typically used for covering short spans. The  
14 number of slab bridges that need further study in the Netherlands is 600. While the calculated  
15 cross-sectional shear capacity might be insufficient, these bridges did not show signs of  
16 distress upon inspection [5]. This observation indicates that reinforced concrete slabs possess  
17 additional sources of capacity that are traditionally not taken into account in the concrete  
18 design codes. In slabs, one of the major sources of additional capacity is the slab's ability for  
19 transverse load redistribution [6] and the influence of the width of the member [7]. A full  
20 literature survey on the shear strength of reinforced concrete slabs [8] and review of  
21 experiments available in the literature [9] confirm the increased shear capacity of reinforced  
22 concrete slabs as compared to beams [10-13].

23 This paper deals with the assessment of reinforced concrete slab bridges based on linear  
24 finite element models, as part of an approach based on Levels of Approximation. For the first

1 time, the distribution width of the peak shear stress is studied experimentally, whereas in the  
2 past, rules of thumb were used.

### 3 **2. Levels of Assessment**

4 In the 2010 *fib* Model Code [14], a new concept is introduced for structural engineers: the use  
5 of Levels of Approximation, as shown in Figure 1. Increasing the Level of Approximation  
6 means using a computational technique that requires more time but that gives results that are  
7 expected to be more accurate.

8 The concept of using Levels of Approximation is used for the analysis of the 600 shear-  
9 critical reinforced concrete slab bridges in the Netherlands. The Levels of Approximation for  
10 the assessment of bridges are renamed as “Levels of Assessment”. All bridges that are under  
11 discussion need to be analyzed with Level of Assessment I. The bridges that fulfil the criteria  
12 of Level of Assessment I, or, in other words, when the shear capacity of the cross-section is  
13 larger than the shear stress resulting from the applied loads, are not analyzed further. The  
14 bridges with one or more cross-sections that do not fulfill the requirements of Level of  
15 Assessment I are reanalyzed with Level of Assessment II. As before, the bridges with cross-  
16 sections that are found to be sufficient with Level of Assessment II, are not studied further.  
17 The bridges with one or more cross-sections that do not fulfill the Level of Assessment II  
18 criteria are taken into Level of Assessment III. This procedure is repeated throughout the  
19 higher Levels of Assessment.

20 For assessment of the existing reinforced concrete slab bridges, Level of Assessment I  
21 consists of a spreadsheet-based calculation, which is similar to a hand calculation. This  
22 approach is called the “Quick Scan” [15, 16]. The shear stress resulting from the acting forces  
23 is determined by using superposition of the individual contributions. The shear stress from  
24 the distributed loads is determined based on static equilibrium and the shear stress from

1 concentrated loads is based on a  $45^\circ$  load distribution in the plane of the slab so that the  
2 effective width in shear over which this load is acting can be determined. The shear capacity  
3 is determined by NEN-EN 1992-1-1:2005 [2] with a lower bound  $v_{min}$  as derived by  
4 Walraven [17]. The spreadsheet can read in all information from the database of the bridges  
5 under study, and as output it gives the maximum Unity Check (the ratio between the design  
6 value of the applied shear stress resulting from the loads (composite dead load and live load)  
7 and the shear resistance as prescribed by the Eurocode [2]), of the critical cross-section, per  
8 bridge section span. This method allows for a fast identification of which bridges can be  
9 considered sufficient and which bridges need further study. A number of conservative  
10 assumptions have been made in the Quick Scan: the effective width of the concentrated loads  
11 is determined per axle of the design truck, and the same effective width is used for both axles  
12 of the design truck (giving a smaller effective width to the second axle than when  $45^\circ$  load  
13 spreading would be applied) [18]. A smaller effective width will result in a larger shear stress  
14 for the same applied live load model. Moreover, the larger distributed live load in the first  
15 lane with slow truck traffic is distributed over only a small portion of the width, which is a  
16 more conservative approach than using a distribution based on Guyon-Massonet [19]. The  
17 thickness of the asphalt layer is conservatively assumed to be 12 mm, which leads to larger  
18 shear stresses than a smaller layer [18].

19 For Level of Assessment II a linear finite element model is used to find the governing  
20 shear stress caused by the applied loads. A linear elastic finite element model is used in Level  
21 of Assessment II instead of a non-linear analysis (Level of Assessment III), which can take  
22 cracking and transverse load redistribution into account and provides a more rigorous  
23 analysis, because it is less time-consuming and can be sufficient for a number of structures  
24 under study. The shear stress caused by the applied loads is compared to the shear capacity of

1 the cross-section, as defined by NEN-EN 1992-1-1:2005 [2] with a lower bound  $v_{min}$  as  
2 described by Walraven [17]. The design tandems have to be moved in such a way that the  
3 most unfavorable position is found, resulting in the largest possible shear stress for the given  
4 loads. The output of the model is the distribution of the shear stress over the width at the  
5 support. The peak shear stress in this distribution needs to be averaged over a certain distance  
6 to achieve the shear stress that can be compared to the code-prescribed shear capacity. The  
7 distribution width is typically determined based on rules of thumb and local practice. In The  
8 Netherlands, a multiple of the effective depth to the longitudinal flexural reinforcement,  $d_l$ , is  
9 used. The recommendations in this paper are developed to be used with a linear finite element  
10 program for a Level of Assessment II evaluation and to help engineers identify the governing  
11 shear stress.

12 Higher Levels of Assessment include non-linear finite element models and probabilistic  
13 analysis for Level of Assessment III, and proof loading for Level of Assessment IV. These  
14 higher levels are outside of the scope of this paper. Guidelines for the use of non-linear finite  
15 element models have been developed [20] and have been applied to the discussed slab shear  
16 experiments [21]. Proof loading of slab bridges is currently being studied. Preliminary results  
17 can be found elsewhere [22-26].

### 18 **3. Description of experiment**

#### 19 ***3.1. Test setup***

20 Experiment S25T1 is used for comparison to a linear finite element model to come up with  
21 recommendations for the distribution width as a multiple of  $d_l$ . This experiment is part of a  
22 series of experiments from Delft University of Technology designed to better understand the  
23 shear capacity of reinforced concrete slabs under concentrated loads close to supports. In a

1 first series, 18 slabs and 12 slab strips were tested under a concentrated load close to the  
2 support [7, 27] to study the difference in shear behavior between beams and slabs. In a  
3 second series, an additional 8 slabs were tested under a combination of a concentrated load  
4 close to the support and a line load [28] to verify if the hypothesis of superposition is valid at  
5 the ultimate limit state. S25 was a specimen pertaining to the second series of experiments,  
6 but during the first experiment on this slab, S25T1, only a single concentrated load was used,  
7 which is the loading configuration from the first series of experiments. S25T1 is thus the only  
8 experiment with the test setup of the second series, which includes the use of load cells  
9 distributed over the support, but with the loading configuration of the first series of  
10 experiments. As such, only this single experiment is suitable for the analysis of the  
11 distribution width of the concentrated load. Only one test as such is available, as S25T1 was  
12 originally carried out to verify that the results and recommendations from the first series are  
13 still valid when a slightly different test setup (as used in the second series) was used. The  
14 question with regard to the distribution width for application to the second Level of  
15 Approximation only arose after carrying out all experiments and dismantling the test setup.  
16 Therefore, it was not possible to carry out additional experiments. The reader should keep  
17 this limitation in mind.

18 A sketch of the test setup for S25T1 is shown in Figure 2a and a photograph is given in  
19 Figure 2b. The size of the slab was 5 m  $\times$  0.3 m  $\times$  2.5 m, representing a half-scale continuous  
20 solid slab bridge. The span length was 3.6 m.

21 The line supports consisted of a steel beam (HEM 300 with  $h = 300$  mm) of 300 mm  
22 wide, on which 7 steel bearings of 350 mm  $\times$  280 mm  $\times$  45 mm provided with load cells (or  
23 dummy blocks) and hinges were placed. The load cells were used on the support close to  
24 which the experiment was carried out, and the other support was equipped with dummy

1 blocks. On top of the steel bearings, a steel strip of 100 mm × 15 mm × 2500 mm and 7 strips  
2 of felt N100 of 100 mm × 5 mm × 280 mm were used. The felt properties of felt type N100  
3 have been tested previously [29] and the compression stiffness was found to be 6.5  
4 Nmm/mm<sup>3</sup>.

5 Three vertical prestressing bars couple the cantilevering end of the slab past support 2 to  
6 the laboratory floor (Fig. 2a), creating a moment over support 2 and thus simulating a  
7 continuous support (CS) for support 2. The prestressing force is applied at the beginning of  
8 every experiment to offset the self-weight of the slab and increases over the course of the  
9 experiment. Load cells measure the force in the prestressing bars so that the moment over  
10 support 2 is known at all time during the experiment. The prestressing at the beginning of the  
11 experiment was 3 × 15 kN.

12 The size of the loading plate was 300 mm × 300 mm. In S25T1, the load is applied in a  
13 displacement-controlled way in the middle of the width, close to the simple support. The  
14 center-to-center distance between the load and the support,  $a$ , was 600 mm in the experiment,  
15 as shown in Fig. 2a.

### 16 **3.2. Tested specimen**

17 Deformed bars of steel S500 with a diameter of 20 mm and a yield strength  $f_{ym} = 542$  MPa  
18 and ultimate strength  $f_{um} = 658$  MPa as well as bars with a diameter of 10 mm and  $f_{ym} = 537$   
19 MPa and  $f_{um} = 628$  MPa were used. The main longitudinal reinforcement of S25 consisted of  
20  $\phi 20$  mm bars spaced at 125 mm on center, and the transverse flexural reinforcement  
21 consisted of  $\phi 10$  mm bars spaced at 125 mm on center. A concrete cover of 25 mm was used,  
22 so that the effective depth to the longitudinal reinforcement equaled  $d_l = 265$  mm. Thus, S25  
23 had a longitudinal reinforcement ratio  $\rho_l = 0.996\%$  and a transverse flexural reinforcement  
24 ratio of  $\rho_t = 0.258\%$ .

1 Normal strength concrete class C28/35 with a maximum aggregate size of 16 mm was  
2 used. The aggregates were glacial river aggregates. The cube concrete compressive strength  
3 at the age of testing (170 days since casting) was  $f_{c,cube} = 58.6$  MPa and the tensile splitting  
4 strength was  $f_{ct} = 4.5$  MPa.

### 5 **3.3. Experimental results**

6 Failure occurred for a maximum concentrated load of  $P_u = 1461$  kN. After the  
7 experiment, mostly longitudinal cracks were observed on the bottom of the slab [30], as well  
8 as some punching damage. Remarkably, and contrarily to earlier experiments with similar  
9 loading conditions [27], on the side faces no cracks were visible, not even flexural cracks.

10 Laser distance finders were used to instrument the slab and measure the deformations. All  
11 measurements can be found in the full test report [30]. The load-displacement diagram of  
12 S25T1 and the forces in the prestressing bars are given in Figure 3. In Figure 4, the most  
13 important deflection plots of the experiments are given. As can be seen from Figures 3 and 4,  
14 the load is applied at a constant rate in a displacement-controlled manner. For the analysis, as  
15 discussed in the next paragraph, a few measurement points were isolated to compare at these  
16 points with the finite element model.

17 At the simple support line, the seven load cells were used to measure the reaction force  
18 and its distribution over the support width continuously during the experiment. For the  
19 current study, nine levels of the continuously increasing applied loading in increments of  
20 10% of the ultimate load (up to 90% of the ultimate load on the slab) are used. The final  
21 interval from 90% of ultimate load to 100% of the ultimate load is not considered because the  
22 behavior of cracking of the concrete and slipping of the concrete with respect to the  
23 reinforcement bar cannot be represented correctly by a linear finite element model. The  
24 measured reaction forces in the load cells are graphically represented in Figure 5a. Not all

1 load cells are activated from the beginning of the experiment because of the small, but  
2 significant, geometric imperfections of the reinforced concrete slab that result in the  
3 unconnected areas between the slab and the load cells. For future experimental work, it is  
4 recommended to use an interface layer between the slab and the support, for example a layer  
5 of plaster of Paris, to ensure a better contact between the slab and the support.

## 6 **4. Finite element model of experiment**

### 7 *4.1. Description of finite element model*

8 The experiment was simulated in Diana, Release 9.4.4 [31]. The supports were modeled as  
9 3D solid elements. Figure 6 shows a rendering of the model with the different elements  
10 labelled.

11 The concrete slab was modelled as shell elements with a Young's modulus of 31.6  
12 GPa in the main direction and 10.5 GPa in the other directions; with a shear modulus of 13.7  
13 GPa in the main direction and 4.6 GPa in the other directions; with a Poisson's ratio of 0.15  
14 and with a density of 25 kN/m<sup>3</sup>. The Poisson ratio is set to 0.15, according the Dutch  
15 guidelines for modelling of concrete [20]. Of course, the Poisson ratio should be reduced  
16 when serious cracking occurs, with the reduction in relation to the crack width. Orthotropic  
17 behaviour is already foreseen, so reducing the Poisson ratio to zero is more or less double.  
18 These analyses are all linear static, and the Poisson reduction is available and highly  
19 recommended in nonlinear analysis. Gauss point values for the stresses can be recommended.  
20 The slab behaviour simulation by a nonlinear simulation, which is not included in this paper,  
21 but can be found elsewhere [21], shows until about 80% of the ULS load, that the Poisson  
22 ratio can be set to 0.15. After this 80% ULS criteria some Poisson ratios belonging to  
23 severely cracked elements need to be modified.

1           In between the solid elements and the shell elements, interface elements representing  
2 the layer of felt were used. The interface elements have a normal stiffness and shear stiffness.  
3 The normal stiffness is calculated as the Young's modulus of the concrete, divided by the  
4 thickness of the interface element. The shear stiffness is taken as 1% of the normal stiffness.

5           The reinforcement bars were modeled as embedded steel bars. For the model, 40% of  
6 orthotropy was assumed.

7           Mapped meshing was used. The FE mesh is set up with the dimension based on the  
8 thickness of the slab. The Rijkswaterstaat NLFEA recommendation [20] tells us that the  
9 length and width of a single slab element should be less or equal to half of the thickness of  
10 the slab. In this way, the problem of missing local forces at the edges of the slab can be  
11 avoided. The resulting mesh is shown in Fig. 6b for the top view and Fig. 6c for the side  
12 view. The extrapolation to nodal stress values is used and permitted for linear finite element  
13 models, whereas this practice is not recommended for nonlinear finite element models.

14           The load was modeled as a uniformly distributed load applied to a steel plate of 300  
15 mm  $\times$  300 mm, as in the experiment. Solid elements were used to model the loading plate.  
16 All steel elements had a Young's modulus of 200 GPa and a Poisson's ratio of 0.3. In the  
17 experiment, the slab was not resting on all bearings due to initial geometric imperfections.  
18 Based on the measurements of the reaction forces in the supports (Fig. 5), a phased activation  
19 of the supports was implemented into the model.

20           These choices for modeling results in 42 elements for the width of the slab by 71  
21 elements for the length of the slab. The supports were modeled as steel beams with 2  
22 elements over the height, 2 elements over the width and 42 elements over the length. The  
23 interface was modeled as 2 elements over the width and 42 elements over the length. The  
24 three prestressing bars were taken into account.

1           The presented linear finite element model mostly is based on choices that are standard  
2 in current engineering practice. However, to study the finite element modeling of reinforced  
3 concrete slabs, both the use of solid and plate elements was explored. Additionally, to  
4 develop guidelines for the modeling of reinforced concrete slabs, several experiments tested  
5 in the Stevin II Laboratory of Delft University of Technology as well as from the literature  
6 were modeled with linear and non-linear finite element models [20, 21, 32-34]. Moreover, the  
7 required safety format was studied in the cited studies, analyzing both mean values to  
8 simulate experiments and the safety format from the *fib* Model Code [14] for the application  
9 to the assessment practice. These recommendations form the background for the presented  
10 modeling.

#### 11 ***4.2. Analysis and verification of model***

12 Before the results of the finite element model can be used for comparison to the experiments,  
13 the measured reaction forces at the load cells are used to check if the model represents the  
14 experiment satisfactorily. The measured reaction forces as shown in Figure 5a can be  
15 compared to reaction forces in the model. The same nine intervals of the applied load are  
16 considered. The resulting reaction forces from the model are presented in Figure 5b. The  
17 reaction forces in the experiment and model are similar, as can be seen from comparing  
18 Figures 3a and b. This observation indicates that the performance of the finite element model  
19 is satisfactory and that the model can be used to study the distribution width of the peak shear  
20 stresses and formulate a recommendation for the use with Level of Assessment II. The  
21 reaction forces over the support are asymmetric as a result of the lack of contact at certain  
22 points between the slab and the support. Whereas this experimental observation caused an  
23 extra challenge in modeling the slab, it is not expected that the asymmetric support reactions  
24 pose a limitation to the results. Moreover, the loading on reinforced concrete slab bridges

1 according to the Eurocodes for assessment is asymmetric, with the heaviest truck in the first  
2 lane [35].

### 3 **5. Analysis of experimental results**

#### 4 ***5.1. Results of the experiment***

5 The analysis of the results of the experiment and the linear elastic finite element model aim at  
6 comparing the shear stress distributions and formulating recommendations for the distribution  
7 width around the peak shear stress in the finite element model. The distribution width will be  
8 expressed as a multiple of the effective depth to the longitudinal reinforcement  $d_l$ .

9 First, the measured reaction forces over the width of the slab in experiment S25T1 are  
10 analyzed. To carry out the shear stress analysis, the reaction forces need to be converted into  
11 shear stresses. This analysis is carried out at two levels of the ultimate load: 40% of the  
12 ultimate load or with an applied concentrated load of 585 kN, assuming the Serviceability  
13 Limit State (SLS) conditions, and 90% of the ultimate load or with an applied concentrated  
14 load of 1314 kN, assuming the Ultimate Limit State (ULS) conditions. The calculation  
15 procedure here is illustrated for the case of an applied concentrated load of 1314 kN. Since  
16 the reaction forces in the experiment are measured only at seven discrete positions over the  
17 slab width, it is assumed that the reaction force is distributed uniformly over the influence  
18 length of the support. Because of the geometry, the influence length of the load cells is 358  
19 mm. A sketch of the situation, indicating the distribution over  $2d_l$  and  $4d_l$  is given in Figure 7  
20 and Figure 8 respectively. The length of  $2d_l$  equals 530 mm and the length of  $4d_l$  equals 1060  
21 mm. These distances are assumed around the center of the middle load cell (FS3), of which  
22 the center line coincides with the center of the width of the slab. For a concentrated load of  
23 1314 kN, the largest reaction force in the experiment was found in bearing FS3. In Figure 7, a

1 distance of  $d_l$  is indicated as the distribution width on each side of the center of FS3. The total  
2 width of the slab was 2500 mm, and the distance  $2d_l$  goes from  $x = 985$  mm to  $x = 1515$  mm  
3 along the width of the slab, as shown in Figure 7. For  $4d_l$  the positions are  $x = 720$  mm to  $x =$   
4  $1780$  mm, as shown in Figure 8.

5 The total applied reaction force,  $F_{tot,2d}$  over  $2d_l$  is:

$$6 \quad F_{tot,2d} = FS3 + \frac{86 \text{ mm}}{358 \text{ mm}}(FS2 + FS4) = 580 \text{ kN} \quad (1)$$

7 The shear stress over  $2d_l$ ,  $\tau_{2d}$ , is found by dividing the force  $F_{tot,2d}$  by the area. This area has a  
8 height of  $d_l$  and a width of  $2d_l$ :

$$9 \quad \tau_{2d} = \frac{F_{tot,2d}}{2d_l^2} = \frac{580 \text{ kN}}{2(265 \text{ mm})^2} = 4.13 \text{ MPa} \quad (2)$$

10 A similar approach is used to determine the applied reaction force  $F_{tot,4d}$  over  $4d_l$ :

$$11 \quad F_{tot,4d} = FS3 + \frac{351 \text{ mm}}{358 \text{ mm}}(FS2 + FS4) = 739 \text{ kN} \quad (3)$$

12 Similarly, the shear stress  $\tau_{4d}$  over  $4d_l$  can be defined as:

$$13 \quad \tau_{4d} = \frac{F_{tot,4d}}{4d_l^2} = \frac{739 \text{ kN}}{4(265 \text{ mm})^2} = 2.63 \text{ MPa} \quad (4)$$

14 At 40% of the ultimate load (585 kN) the largest reaction force occurs at load cell FS5, as can  
15 be observed in Figure 5a, due to the phased activation of the supports. A similar procedure as  
16 described for a load of 1341 kN is followed, but now the distribution is considered around the  
17 center of load cell FS5. Assuming a distribution width of  $2d_l$ , a total force  $F_{tot,2d} = 212$  kN is  
18 found, resulting in a shear stress  $\tau_{2d} = 1.51$  MPa. Assuming a distribution width of  $4d_l$ , a total  
19 force  $F_{tot,4d} = 244$  kN is found, resulting in a shear stress  $\tau_{4d} = 0.87$  MPa.

## 1 **5.2. Results of the finite element model**

2 In a next step, the corresponding shear stresses from the linear finite element model are  
3 computed. These stresses are then compared to the results of the experiment as calculated in  
4 the previous step to formulate a recommendation for the distribution width. The output of the  
5 finite element model allows for different ways of analyzing the results. To obtain the shear  
6 stress over the distribution width, the following two methods can be used:

- 7 1. Integration of the shear stresses over the considered distribution width to determine  
8 the shear force at the support, which is then divided by the distribution width and the  
9 effective depth, or
- 10 2. Analysis of the distribution of the reaction forces in the discrete supports, in the same  
11 way as the experimental results were analyzed (Fig. 7, Fig. 8).

12 For the first method, the shear stress distribution over the support is analyzed. An example is  
13 given in Figure 9, for a concentrated load of 585 kN. In Figure 9, the distance  $2d_l$  and  $4d_l$  is  
14 shown around the center of the slab as well as around the peak value of the stress distribution.  
15 For the analysis, the position of the peak value of the stress distribution is used as the center  
16 of the uniform stress distribution, as is typically done in practice. Integrating the shear stress  
17 obtained in the finite element model over  $2d_l$  around the peak shear stress results in  $\tau_{2d} = 1.30$   
18 MPa and integrating over  $4d_l$  results in  $\tau_{4d} = 1.10$  MPa. A similar procedure is followed for  
19 90% of the maximum load, for an applied concentrated load of 1314 kN.

20 For the second method, the reaction forces at the locations of the load cells in the finite  
21 element model are studied. These reaction forces are given in Figure 5b. For a load of 585  
22 kN, the peak reaction force is found in FS4, which differs slightly from the peak position in  
23 the experiment in load cell FS5. If the method as described for the measured reaction forces  
24 is used around the peak for FS4, then  $F_{tot,2d} = 196$  kN and the shear stress over  $2d_l$  is found to

1 be  $\tau_{2d} = 1.39$  MPa. For a distribution over  $4d_l$ , the total load  $F_{tot,4d} = 356$  kN and the shear  
2 stress  $\tau_{4d} = 1.27$  MPa. A similar procedure is followed for 90% of the maximum load, for an  
3 applied concentrated load of 1314 kN.

### 4 ***5.3. Comparison between experiment and finite element model***

5 The previous paragraphs highlighted the calculations at 40% of the maximum load, for a  
6 concentrated load of 585 kN and at 90% of the maximum load, for a concentrated load of  
7 1314 kN. An overview comparing the results in the experiment to those from the finite  
8 element model is given in Table 1 for 40% of the ultimate experimental load (585 kN) and  
9 90% of the ultimate load (1314 kN). The results in Table 1 show that distributing the peak  
10 shear stress over  $4d_l$  gives a conservative estimate of the shear stress in the finite element  
11 model as compared to the shear stress based on the reaction forces in the experiment. The  
12 experimental shear stress is lower than the shear stress based on the finite element model, so  
13 the finite element model results in a conservative estimate of the shear stress due to the  
14 applied loads when a distribution width of  $4d_l$  is used. The results in Table 1 also show  
15 similar results for both approaches to determine the shear stress based on the results in the  
16 finite element program: integration of the stress distribution from the model or using the  
17 resulting reaction forces at the position of the bearings in the model.

### 18 ***5.4. Unity Check of experiment***

19 The previous paragraphs all focused on finding the governing shear stress and the width over  
20 which the peak of the shear stress profile is to be distributed. For an assessment, the  
21 governing shear stress is compared to the shear capacity according to NEN-EN 1992-1-  
22 1:2005 [2] with  $v_{min}$  as defined by Walraven [17] in order to find the Unity Check and see if  
23 the cross-section fulfills the criteria. For S25T1 the shear capacity of the cross-section can be  
24 found as:

$$1 \quad v_{Rd,c} = 0.12k(100\rho_l f_{ck})^{1/3} = 0.12 \times 1.87(0.996 \times 28 \text{MPa})^{1/3} = 0.68 \text{MPa} \quad (1)$$

$$2 \quad v_{min} = \frac{1.08k^{3/2} f_{ck}^{1/2}}{f_{yk}^{1/2}} = \frac{1.08 \times 1.87^{3/2} \times 28^{1/2}}{500^{1/2}} = 0.65 \text{MPa} \quad (2)$$

3 The design shear stress is the maximum of  $v_{min}$  and  $v_{Rd,c}$  and is thus  $v_{Rd,c} = 0.68$  MPa. This  
4 value can be compared to the shear stress over  $2d_l$  and  $4d_l$ , for example at 40% of the  
5 experimental ultimate load based on the results from integrating the stresses over the support  
6 in the finite element model. The value at 40% is considered to be more representative of the  
7 shear stresses that develop based on the loads for which the cross-sections are assessed,  
8 because of the large loads that were found in the slab shear experiments. The governing shear  
9 stress is then  $\tau_{2d} = 1.30$  MPa with distribution over  $2d_l$  and  $\tau_{4d} = 1.10$  MPa with distribution  
10 over  $4d_l$ . As a result, the Unity Check based on a distribution width over  $2d_l$  equals 1.91 and  
11 based on a distribution width over  $4d_l$  equals 1.62.

12 The resulting Unity Checks indicate the large inherent conservatism in the code as  
13 compared to the experimental result, as noted previously in the slab shear research [27]. Also,  
14 the Unity Checks show that using a distribution width over  $4d_l$  leads to a smaller  
15 underestimation of the capacity, and is thus to be preferred. This observation is an additional  
16 benefit of using the  $4d_l$  distribution width, but not the governing criterion for the choice of the  
17 distribution width.

### 18 **5.5. Higher Levels of Approximation**

19 For Levels of Approximation III, non-linear finite element models are used. The approach  
20 followed based on a non-linear finite element model is different from the approach outlined  
21 in this paper based on a linear finite element model, and is also different from the Quick Scan  
22 approach. For both methods, the capacity is taken based on the formulas from the code,

1 whereas the model provides the resulting shear stress caused by the loads. In a non-linear  
2 finite element model, a different approach is followed. The load is applied in increments to  
3 have a load-controlled situation, or by applying increments of displacement at the load, to  
4 have a displacement-controlled situation, which is to be preferred. In each load step, the  
5 model runs and it is explored if cracking occurs. If cracking occurs, the stiffness of the model  
6 in the cracked elements will be reduced for the next load step. As such, a non-linear finite  
7 element model is close to the execution of an experiment, and results in a load-displacement  
8 diagram. The material model for the concrete (see Figure 10) this case can then be based on a  
9 total strain rotating crack model, with exponential softening in tension and parabolic behavior  
10 in compression, with a variable Poisson's ratio, and an increase in compressive strength due  
11 to lateral confinement. The material model for the reinforcement is based on hardening  
12 plasticity, see Figure 11. For the steel loading plate, a linear elastic behavior can be assumed.

13         In terms of elements, for the concrete 20-node solid elements are recommended, using  
14 five elements over the slab height. For the reinforcement bars, embedded truss elements with  
15 two Gauss integration points along the axis of the element are recommended. The  
16 prestressing bars can be modeled as 2-node truss elements, and the steel plate can be modeled  
17 using 20-node solid elements.

18         An example of application is shown in Figure 12. The crack strain values are shown at  
19 the maximum load. A strip of the slab (isolated only in the post-processing stage) is shown,  
20 so that the crack strain values can be studied more closely. It can be seen that the inclined  
21 cracking, indicating shear failure can be captured by the non-linear finite element model.

22         Recommendations for the use of non-linear finite element models for the assessment  
23 of reinforced concrete slab bridges are being finalized, and will be published shortly [32].

1 Upon publication of these guidelines, and the agreement on the procedures, the methods for  
2 Level of Assessment III will be applied at a larger scale.

3 The highest Level of Assessment [36] includes the use of proof load tests [37]. This  
4 research is currently being carried out. In these pilot proof load tests, measurements are  
5 applied over the width of the support, to verify the distribution width in existing bridges. This  
6 topic is currently being evaluated.

## 7 **6. Case Study**

8 In this paragraph, an example reinforced concrete solid slab bridge is analyzed using the  
9 Quick Scan method, Level of Assessment I, as well as using a finite element model, Level of  
10 Assessment II, to find the governing shear stress. In the Level of Assessment II approach, the  
11 recommended distribution width for the peak shear stress of  $4d_l$  is used. For both methods,  
12 the analysis of the cross-section is based on the Unity Check, the ratio of the shear stress  
13 caused by the applied loads to the shear capacity according to NEN-EN 1992-1-1:2005 [2].

14 It needs to be noted upfront that one of the differences between the Level of Assessment I  
15 method and the Level of Assessment II method is that the Quick Scan approach results in  
16 Unity Checks for 3 cross-sections, while the finite element results can be used to verify every  
17 cross-section in the studied spans.

18 The case under study is a reinforced concrete solid slab bridge built in 1959. This bridge  
19 has 4 spans, with end spans of 10.1 m and mid spans of 14.4 m and a width of 10 m of which  
20 6 m carries traffic. The depth of the slab varies transversely from 530 mm to 470 mm. The  
21 depth varies longitudinally from 550 mm at the supports to 530 mm at mid span. Plain  
22 reinforcement bars of steel QR24 with a yield strength of 240 MPa are used. The cover to the  
23 reinforcement is 25 mm. The sagging moment reinforcement ratio in the end span is  $\rho_l =$

1 0.69% and the hogging moment reinforcement ratio at the mid supports is  $\rho_l = 0.78\%$ . As for  
2 all existing slab bridges from The Netherlands owned by the Dutch Ministry of Infrastructure  
3 and the Environment of which no test results about the concrete strength are available, the  
4 characteristic cylinder compressive strength of the concrete can be assumed as  $f_{ck} = 35$  MPa  
5 [38].

6 For the considered case, the governing cross-section in the Quick Scan is at support 2-3  
7 (close to the mid support in the second span) with a shear stress due to composite dead load  
8 and live loads from Load Model 1 at the edge of the support  $v_{Ed} = 0.68$  MPa and a shear  
9 capacity  $v_{Rd,c} = 0.91$  MPa (the lower bound shear capacity  $v_{min}$  [17] is governing over  $v_{Rd,c}$   
10 from NEN-EN 1992-1-1:2005 [2]). These stresses result in a Unity Check value of UC =  
11 0.74.

12 Consequently, a linear finite element model of the considered bridge is used as a Level of  
13 Assessment II method. The slab is modeled as a plate with shell elements. The variable depth  
14 in the transverse direction is taken into account, while the variable depth in the longitudinal  
15 direction is not considered. The governing shear force in the finite element model is found to  
16 be 278 kN/m. For the shear capacity the lower bound of the shear stress  $v_{min}$  [17] is again  
17 found to be governing for the QR24 steel, and results in  $V_{min} = 438$  kN/m. The resulting  
18 Unity Check at the governing section is then UC = 0.63.

19 This comparison shows that the goal of the finite element model as a higher Level of  
20 Assessment than the Quick Scan method to be a more selective assessment tool is met. The  
21 Quick Scan is based on a series of conservative assumptions that cover the entirety of all  
22 solid slab bridges owned by the Dutch Ministry of Infrastructure and the Environment. For  
23 individual cases, the assumptions can often prove to be overly conservative. This observation  
24 is reflected by the smaller Unity Check found based on the shear stress from the finite  
20

1 element model, and is according to the philosophy of the Levels of Approximation as shown  
2 in Figure 1.

### 3 **7. Discussion**

4 In experiment S25T1 a flat slab is supported by steel bearings equipped with load cells and  
5 hinges. This support condition is different from the practical case of existing solid slab  
6 bridges. In a real bridge, an edge beam is often cast onto the slab, which results in an even  
7 better distribution of the load over the support. In this experiment, the setup with load cells  
8 and hinges was used to study the distribution of the reaction forces at the support. However,  
9 because of the use of a line of bearings, the resulting support condition is almost equal to a  
10 line support. It however is not cast integrally to the slab, which reduces the transverse  
11 distribution capacity. The recommendation of the distribution width to be  $4d_l$  based on the  
12 comparison between the experiment and the finite element model is thus a conservative  
13 approach.

14 For the modeling of an existing bridge with a linear finite element model, the use of shell  
15 elements for the edge beam, instead of 3D solid elements for the support as used in this study,  
16 is sufficient. This study used 3D solid elements to model the particular support layout used in  
17 the experiment to determine the reaction forces over the width of the slab.

18 In experiment S25T1, no (flexural) cracks were observed on the side face of the slab. This  
19 observation indicates that less transverse load redistribution was activated than in other slab  
20 shear experiments. Therefore, the shear stress distribution at the support is more concentrated  
21 around the peak load than when more transverse load redistribution is activated. As such, the  
22 chosen experiment is a conservative lower bound for the studied case of slab bridges  
23 subjected to concentrated and distributed loads.

1 The experiment has been carried out with a concentrated load representing the wheel print  
2 that is used in Load Model 1 of NEN EN 1991-2:2003 [1]. The influence of the size of the  
3 concentrated load and on the shear capacity on the shear stress distribution is known [27] .  
4 Therefore, the recommended distribution width of  $4d_l$  is to be used with concentrated wheel  
5 loads of the size as used in Load Model 1 of NEN EN 1991-2:2003 or similar wheel prints.

6 The shear-span-to-depth ratio used in the experiment is  $a/d_l = 2.26$ . This short distance  
7 ensures that the stress distribution at the support does not differ much from the stress  
8 distribution at the cross-section containing the concentrated load. For practical use, the cross-  
9 section with the concentrated can thus be analyzed, regardless of the shear span. An  
10 additional reason for using  $a/d_l = 2.26$  is that this distance closely corresponds to the  
11 recommended distance for assessment of reinforced concrete slab bridges, where the first  
12 truck is placed at  $a_v/d_l = 2.5$  [39].

13 The reader should note that the presented work is only applicable to solid slab bridges.  
14 For floor slabs of buildings or footings, a different behavior can be expected. The behavior of  
15 slab bridges is governed by the span direction, while for floor slabs of an even floor plan,  
16 both the longitudinal and transverse direction can become equally important. Moreover, the  
17 results of the current analysis refer to bridges on line supports or on a closely spaced series of  
18 bearings, so that punching of the bearings does not become a governing failure mode. In floor  
19 slabs, punching of the columns can become the governing failure mode and influences the  
20 flow of shear stresses.

## 21 **8. Summary and conclusion**

22 The principle of Levels of Approximation, as used in the recently published *fib* Model Code  
23 2010 is applied to assessment of reinforced concrete slab bridges, resulting in Levels of  
24 Assessment. Increasing the Level of Assessment means using a computational technique that  
22

1 requires more time but that gives results that are expected to be more accurate. For the shear  
2 assessment of reinforced concrete solid slab bridges, Level of Assessment I is an analysis  
3 with the Quick Scan method, a conservative, fast, spreadsheet-based tool that can quickly  
4 identify which bridges contain cross-sections that need further study. Level of Assessment II  
5 is an analysis in which the shear stress at the support caused by the applied loads is  
6 determined with a linear finite element model. The result in the program is a shear stress  
7 distribution over the width of the support. As always in finite element models, the peak needs  
8 to be smoothed out. This paper analyzed over which width the peak shear stress at the support  
9 can be distributed for the shear analysis. Previously, rules of thumb were used for this  
10 distribution width. This study quantifies the distribution width for the first time based on  
11 experimental evidence.

12 To study the required distribution width in the finite element model, a comparison is  
13 made between an experiment and a linear finite element model. The experiment S25T1 was a  
14 test of a reinforced concrete solid slab subjected to a single concentrated load close to the  
15 support. The support was equipped with seven load cells to measure the reaction force profile  
16 over the width of the support. These elements were used as well in the linear finite element  
17 model for this study, in which the slab was modeled with shell elements.

18 The effect of distributing the peak shear stress over a distance  $2d_l$  and  $4d_l$  over the  
19 support are studied with the experimental results and the results from the finite element  
20 model. The analysis showed that a distribution width of  $4d_l$  should be used for smoothing out  
21 the peak shear stress found in a linear finite element program. When the Unity Check of the  
22 experiment is calculated, the large inherent conservatism of both the Level of Assessment I  
23 and Level of Assessment II is seen.

1            Finally, a case study is carried out, in which the application of Level of Assessment I  
2 and Level of Assessment II is studied, and it is found that the approach with the Levels of  
3 Assessment works, since Level of Assessment I gives a more conservative Unity Check than  
4 Level of Assessment II.

5

## 6 **Acknowledgements**

7 The authors wish to express their gratitude and sincere appreciation to the Dutch Ministry of  
8 Infrastructure and the Environment (Rijkswaterstaat) for financing this research work.

## 9 **List of notation**

10	$a$	center-to-center distance between the load and the support
11	$a_v$	face-to-face distance between the load and the support
12	$d_l$	effective depth to the longitudinal reinforcement
13	$f_{c,cube}$	cube compressive strength of the concrete
14	$f_{ck}$	characteristic concrete cylinder compressive strength
15	$f_{ct}$	cube splitting strength of concrete
16	$f_{ym}$	yield strength of steel
17	$f_{um}$	ultimate tensile strength of steel
18	$h$	height
19	$k$	size effect factor
20	$s$	displacement
21	$t$	time
22	$v_{Ed}$	governing shear stress in cross-section from the applied loads
23	$v_{min}$	lower bound for shear capacity

1	$v_{Rd,c}$	shear capacity of cross-section as prescribed by NEN-EN 1992-1-1:2005 [2]
2	$x$	position along the width of the slab
3	$F$	applied load
4	$F_i$	measured force on the prestressing bars, with $i$ the number of the bar (1, 2 or 3).
5	$F_{max}$	maximum concentrated load in the experiment
6	$F_{tot,2d}$	total applied reaction force over $2d_l$
7	$F_{tot,4d}$	total applied reaction force over $4d_l$
8	$P_u$	maximum applied load in experiment
9	UC	Unity Check value
10	$V_{min}$	minimum shear capacity
11	$\rho_l$	longitudinal reinforcement ratio
12	$\rho_t$	transverse reinforcement ratio
13	$\tau_{2d}$	resulting shear stress over $2d_l$
14	$\tau_{4d}$	resulting shear stress over $4d_l$

1 **List of tables and figures**

2 **List of Tables:**

3 **Table 1** – Comparison between the results from the experiment and the results from the finite  
4 element analysis.

5 **List of Figures:**

6 **Fig. 1** – Principle of Levels of Approximation as introduced in the *fib* Model Code 2010 [14].

7 **Fig. 2** – Overview of test setup for experiment S25T1: (a) sketch of top view; (b) photograph  
8 of setup.

9 **Fig. 3** – Test results for S25T1: (a) Load-displacement diagram; (b) Force in prestressing bars  
10 during experiment.

11 **Fig. 4** – Deflection profiles for S25T1: (a) Deflection at selected points in time in the span  
12 direction; (b) Deflection at selected points in time across the width at the position of the  
13 concentrated load; (c) Deflection over the simple support; (d) Deflection over the continuous  
14 support.

15 **Fig. 5** – (a) Measured reaction forces at nine identified load levels in S25T1; (b) Resulting  
16 reaction forces at nine identified load levels for the finite element model of S25T1 using  
17 phased activation of the supports.

18 **Fig. 6** – Overview of the finite element model of S25T1: (a) general overview; (b) top view  
19 showing mesh; (c) side view showing mesh.

20 **Fig. 7** – Distribution of the measured reaction force over  $2d_l$

21 **Fig. 8** – Distribution of the measured reaction force over  $4d_l$

- 1 **Fig. 9** – Distribution of the shear stress over the support obtained from the finite element
- 2 model. Dashed lines show  $2d_l$  and  $4d_l$  around the peak of the shear stress distribution, and full
- 3 lines show these distances around the center of the slab.
- 4 **Fig. 10** – Stress-strain curve for concrete to be used in non-linear finite element model [32].
- 5 **Fig. 11** – Stress-strain curve for reinforcement steel of diameter 20 mm to be used in non-
- 6 linear finite element model [32].
- 7 **Fig. 12** – Example of crack strains at peak load for a strip of a slab, isolated from the full
- 8 model to analyze the crack strains [32].

1 **Table 1- Comparison between the results from the experiment and the results**  
 2 **from the finite element analysis.**

Concentrated load	585 kN		1314 kN	
Shear stress	$\tau_{2d}$ (MPa)	$\tau_{4d}$ (MPa)	$\tau_{2d}$ (MPa)	$\tau_{4d}$ (MPa)
Measurements	1.51	0.87	4.13	2.63
Model, integrating stresses	1.30	1.10	3.28	2.70
Model, reaction forces	1.39	1.27	3.25	2.60
