1 **ABSTRACT**

2 Dutch road designers and safety experts are searching for more quantitative methods to evaluate
3 the safety of a (proposed) weaving section than the traditional methods of expert judgement and
4 use of accident records. An alternative would be to determine safety using VISSIM
5 micro-simulation models in combination with the Surrogate Safety Assessment Model (SSAM).
6

7 SSAM calculates the number of conflicts (i.e. observable situations in which two or more
8 road users approach each-other resulting in a potential collision risk) that occurred in a
9 micro-simulation model using surrogate safety measures. This study evaluates this method for
10 Dutch weaving sections by comparing the number of conflicts observed from VISSIM
11 microsimulation models combined with SSAM with the crash rate, and other criteria.
12

13 Nine Dutch weaving sections were selected and ranked based on four criteria: (I) crash rate,
14 (II) conflict rate calculated from VISSIM-simulations using SSAM, (III) number of crashes
15 expected based on a previously developed crash prediction model, and (IV) road safety experts
16 judgement.
17

18 To examine the correlation between the different rankings, the Spearman Rank Correlation
19 Coefficient was calculated between each two rankings. The correlation of 0.567 ($\rho_s = 0.112$)
20 between the crash and conflict rate ranking suggests a reasonable, but insignificant correlation.
21

22 In a sensitivity analysis the effects of some micro-simulation settings, conflict analysis
23 thresholds, and the calibration method were assessed. Although different than expected, extending
24 the calibration process resulted in a weaker correlation. Hence care should be taken when using
25 VISSIM and SSAM to evaluate the conflict rates as (only) safety-predictor of Dutch weaving
26 sections.

32 Crash prediction

1 **Introduction**

2 On highways so-called weaving sections are applied when the point of convergence and point of
3 divergence of two merging and splitting traffic streams are within a short distance. In these
4 weaving sections many vehicles in close proximity switch lanes, which results in a complex
5 driving task, disturbances and conflicts (2). In general, the number of accidents showed to be
6 higher on weaving sections than on other regular freeway sections (3).

7
8 The Dutch national road authority Rijkswaterstaat has guidelines on how to design
9 weaving sections (4,5). However, there are multiple variations in the design, in number of lanes,
10 (as)symmetry, and length. Traffic characteristics such as intensity and vehicle composition also
11 influence the traffic flow (5). Due to the high density of the Dutch road network, weaving sections
12 are applied relatively frequently in the Netherlands, but due to lack of space it is often difficult to
13 design the weaving sections exactly according to the guidelines. Therefore, it is important to
14 understand the implications of deviating from the guidelines on traffic safety.

15
16 When designing weaving sections often multiple design options are possible for one
17 location, and currently in most cases a choice is made based on expert judgement. Therefore, it
18 would be valuable to determine the degree of road safety from a microscopic simulation already
19 during the design process. Some attempts to develop crash modification factors (CMFs) and crash
20 prediction models (CPMs) as alternatives have taken place. For example, Iliadi et al. (1)
21 researched the effects of design elements and traffic flow characteristics on the safety of
22 symmetrical weaving sections in the Netherlands by developing such CPM. However, the
23 derivation of such factors and models is a complex task and not all relevant factors can be
24 included, and also such studies do not focus on vehicles interactions influencing the origin of the
25 accident.

26 Another possibility is to derive the safety of a road section from a micro-simulation using
27 surrogate safety measures. These surrogate safety measures might be a replacement (or addition)
28 for crashes when evaluating the safety of a weaving section. The US Federal Highway
29 Administration (FHWA) developed the Surrogate Safety Assessment Model (SSAM) which can
30 calculate surrogate safety measures from micro-simulations. Thus, micro-simulations can be a
31 good alternative when for a weaving section no accident frequencies are available. A simulation is
32 especially useful when designing a new weaving section as there is no accident data record
33 available at that time.

34 However, such micro-simulations are developed for analysing traffic performance, and not for
35 safety purposes which requires more details regarding vehicle interactions and the inclusion of
36 human factors in the mathematical models. Hence it is uncertain whether SSAM can be used to
37 assess the safety of Dutch weaving sections and how accurate the outcomes of SSAM in
38 combination with VISSIM are. Therefore, the main goal of this research was to determine if
39 combining the micro-simulation model VISSIM and SSAM is a reliable method to predict the
40 traffic safety of Dutch weaving sections.

42 **Literature**

43 In general, the likelihood of being involved in a crash on a freeway is larger on weaving sections
44 than on regular freeway sections (3). The extra high number of lane change manoeuvres in a
45 weaving section with high traffic volume and speeds' variability often results in an increased

1 number of unsafe situations (3). This is due to the weaving traffic resulting in more conflicts
 2 between the vehicles entering and exiting, leading to a more complicated driving task (6).

3
 4 There are two main methods to determine the safety of a weaving section. The most
 5 straightforward method is by analysing historical accident data. However, it is a well-known
 6 problem that official accident statistics are incomplete and biased (7). Of all accidents that occur,
 7 some are not reported to the police. And if the accident is reported, the data is often incomplete or
 8 incorrect. Next to accident counts, also surrogate safety measures can be used to assess safety. The
 9 use of surrogate safety measures and conflicts has become common in recent years.

11 Conflicts and surrogate measures

12 Surrogate safety measures are measures other than actual crash frequency that represent the degree
 13 of safety (8). Most surrogate safety measures use conflicts for that. A conflict is defined by (9) as:

14
 15 *‘an observable situation in which two or more road users approach each other in time and*
 16 *space for such an extent that there is a risk of collision if their movements remain unchanged’.*

17
 18 As illustrated by the pyramid of traffic events (10) shown in Figure 1 conflicts also include
 19 events that do not lead to real crashes. The area of the layer describes the frequency, while the
 20 distance of the layer from the base represents the severity of the events (10). The benefit of
 21 analysing conflicts is that they are observed more frequently than crashes. However, the
 22 disadvantage of using conflicts as a measure for safety is that conflicts do not directly give the
 23 number of accidents that occurs. However, there are some attempts to relate the number of
 24 conflicts and crashes by a formula (11).

26
 27 **Figure 1: Pyramid of traffic events (adapted from (10))**

28 Conflicts can be determined from simulated vehicle trajectories by calculating surrogate
 29 safety measures and assessing whether the calculated value exceeds a certain threshold value or
 30 not. There are many surrogate safety measures available. Two frequently used surrogate safety
 31 measures are the Time to Collision (TTC) and Post Encroachment Time (PET). The TTC indicates
 32 the time span left before two vehicles collide, if nobody takes evasive action. The PET represents
 33 the difference in time between the passage of the 'offending' and 'conflicting' road users over a
 34 common area of potential conflict (12).

1

2 **Safety of Weaving Sections**

3 Some research is available that focusses on the safety of weaving sections in the Netherlands.
4 Already in 1975, Brouwer (13) concluded that the likelihood of a crash increases strongly for
5 shorter weaving sections and weaving sections with a high traffic flow. The latter is not surprising
6 as more vehicles lead to more conflicts and thus more crashes.

7 Iliadi et al. (1) included a sample of 110 symmetric weaving sections distributed over the
8 motorway network in the Netherlands to develop a crash prediction model. Several factors were
9 investigated and were included in the crash prediction model. Factors that were found significant
10 and hence were included in the final model were: the length of the weaving section, AADT, the
11 number of lanes on the main freeway, the share of weaving cars and the location of the weaving
12 section relative to an interchange. Factors that were investigated but not included in the final
13 model were the share of trucks, share of weaving trucks, the interchange type (i.e. cloverleaf,
14 clover-turbine, etc.) and symmetry.

15

16 A larger part of the available literature focuses on data analysis and comparing weaving section
17 types, or on developing crash modification factors and formulae to predict the number of crashes
18 based on certain road design and traffic flow characteristics. However, also simulation models
19 were proposed for assessing traffic safety.

20 Bared (11) emphasized that a major benefit of using simulation models is that there is no
21 need for having a sufficient large accident data base. Moreover, the analysis of accident data is a
22 slow process and results are influenced by the infrequent and random nature of crashes. Bared (11)
23 found a relationship between conflicts per hour and crashes per year. However, there is a need for
24 further research on the interpretation and comparison of such surrogate safety measures.

25 Yang et al. (14) also pointed on the benefit of using micro-simulations over other methods
26 which have limitations due to data availability.

27 Gettman et al. (8) did an evaluation study of SSAM for the FHWA. They performed
28 theoretical tests which compared pairs of simulated design alternatives and a field validation
29 exercises which compared output from the real world to the simulation output. The comparison of
30 design alternatives did not always lead to a clear design preference but rather a trade-off of
31 surrogate safety measures. The simulation conflicts were found to correlate weakly but
32 significantly to the field crash data ($\rho_s = 0.463$). After a sensitivity analysis it was concluded that
33 volume-based prediction models provide a better correlation to field data.

34 Also the research by Huang et al. (15) had as an objective to identify if a combination of
35 the VISSIM simulation model and the SSAM approach provides reasonable estimates for traffic
36 conflicts. Their focus was on signalised intersections. Results of the data analysis showed a
37 goodness-of-fit ($\rho = 0.916$) that indicates a reasonable agreement between safety ranks based
38 simulated and field observed traffic conflicts. However, the simulated conflicts were not good
39 indicators for conflicts that occurred due to unexpected driving manoeuvres such as illegal
40 lane-changes in the real world.

41 El-Basyouny (16) also performed a field validation of SSAM by comparing predictive
42 safety performance capabilities of SSAM with actual accident experience at Canadian signalised
43 intersections. A poor relation was found, and it was concluded that traffic volumes can explain
44 more variation in occurrence of accidents than simulated conflicts obtained from SSAM. The poor
45 relation could be associated to how an intersection was modelled in VISSIM as changing model
46 parameters resulted in considerable variations in the number of conflicts.

1 Essa and Sayed (17) investigated the transferability of calibrated parameters in VISSIM
2 for safety analysis between different sites. Six parameters were identified as important for the
3 safety analysis. Two of them (headway time and desired deceleration) were directly transferable,
4 three (standstill distance, reduction factor for safety distance closed to stop line and start upstream
5 of stop line) were transferable in some degree and one (negative and positive following thresholds)
6 was not transferable. They also mention that first calibrating on delay times and thereafter
7 calibration of driving behaviour parameters results in a stronger correlation between
8 field-measured conflicts and simulated conflicts. By transferring calibrated parameters this
9 calibration procedure can be shortened.

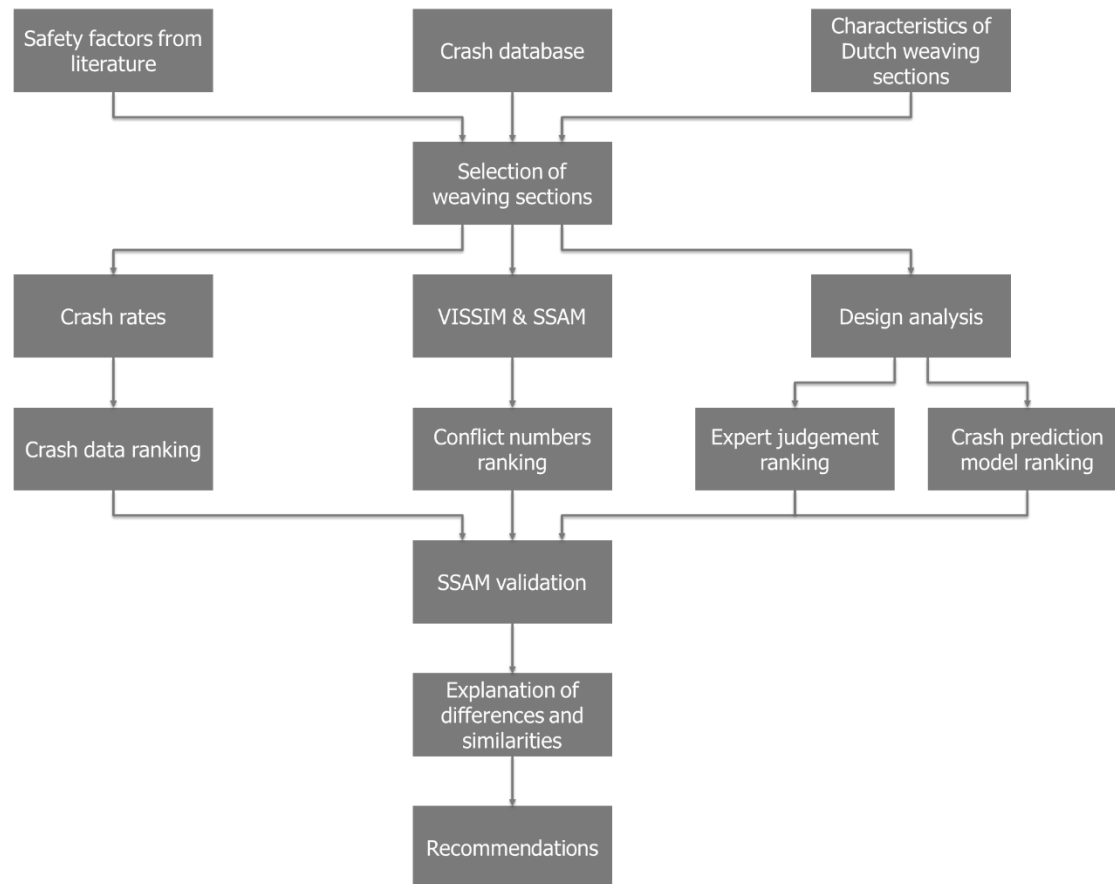

10 Most studies thus applied simulation models and surrogate safety measures on controlled
11 intersections, and not on freeways or weaving sections in particular. Some studies show a
12 reasonable fit between simulated conflicts and observed crashes or conflicts, others indicate that
13 the quality of the simulation model is important and indicate that more research is required.
14

15 **Research methodology**

16 From the literature it becomes clear that using micro-simulations in combination with calculating
17 the number of conflicts might be a good alternative for using crash rates, as it takes a long time to
18 obtain a sufficient reliable and large crash database. SSAM is already applied in some studies as
19 was shown in the literature, however there was no specific focus on the Dutch situations, and on
20 weaving sections in the Netherlands in particular. To investigate whether SSAM in combination
21 with VISSIM microsimulations is sufficient accurate to determine the safety of Dutch weaving
22 sections the following research question is defined:

23
24 *How representative are surrogate safety measures calculated from VISSIM micro-simulations with*
25 *SSAM for predicting the safety of Dutch weaving sections?*
26

27 The research approach is visualized in Figure 2 and further explained in the remainder of this
28 section.
29

1

2 **Figure 2: The research methodology**

3

4 There are some hundreds of weaving sections in the Netherlands. First a weaving section
 5 database was created, including characteristics of these weaving sections such as the configuration
 6 and crash rate (based on number of crashes that occurred between 2012 and 2015).

7 Thereafter a selection of Dutch weaving sections was made. For selecting the weaving sections the
 8 factors that influence the number of crashes were considered. These factors were obtained from the
 9 literature research. Iliadi et al. (1) included the following factors in the CPM developed for the
 10 Dutch situation: length of the weaving section, AADT, weaving width, share of weaving vehicles
 11 and location with respect to the interchange. These factors were considered when selecting the
 12 weaving sections. However, also other factors were considered. At first, it was important that the
 13 design of the weaving section did not change between 2012 and 2015 as then crashes are assigned
 14 to a design that did not exist at that time. Another consideration is that the safety of the weaving
 15 sections was determined by the weaving section itself, and not by environmental characteristics
 16 that could not be included in the simulation model such as the presence of a bridge or height
 17 differences.

18

19 Subsequently this selection was ranked according to four different methods:

20 (1) Based on their crash rate:

21 The crash rate is calculated as the number of crashes that occurred within the influence
 22 area of the weaving section per number of vehicle kilometres. Here the influence area of

1 the weaving section was defined as the weaving section itself and the 150 meters upstream
 2 and downstream of the gores (18). Only the crashes that were registered in the BRON
 3 crash database between 2012 and 2015 were included. The number of vehicle kilometres is
 4 calculated by multiplying the length of the weaving section as registered in the WEGGEG
 5 database by the AADT according to INWEVA 2015;

- 6 (2) Based on the number of conflicts determined from the simulations using surrogate safety
 7 measures:

8 To obtain the conflict rate ranking first all weaving sections were put in VISSIM
 9 micro-simulation models. Correct length and shape of the links was obtained by building
 10 the models on construction maps of the weaving sections. The weaving section itself and
 11 some distance before and after were modelled.

12 A choice was made to simulate one entire workday, as a whole day gives a better
 13 indication of the safety of a weaving section than simulating only the peak-hours. Each
 14 hour was simulated as 900 seconds (i.e. one quarter of the hour).

15 Vehicles were assigned a speed using a desired speed distribution. For each weaving
 16 section a desired speed distribution for cars and HGVs (heavy good vehicles) was
 17 determined from field loop detector data from working days in September 2015. The
 18 traffic intensities per incoming link are derived from loop detector data as well, and are
 19 changed in the models per hour to simulate variations in flows over the day. Weaving
 20 shares (OD matrices) were implemented using static vehicle routes. The required OD
 21 matrices were calculated using a selected link analysis on the Dutch regional model
 22 (NRM) and distinguish between cars and HGVs and are available for the morning peak,
 23 evening peak and off-peak period.

24 The models were calibrated by comparing hourly simulated intensities m to field
 25 intensities c using the GEH-formula (19, 20):

$$26 \quad GEH = \sqrt{\frac{2(m-c)^2}{m+c}} \quad (1)$$

27 Intensities, ramp-shares and OD-matrices were changed if the GEH statistic indicated a
 28 too large deviation (i.e. $GEH > 10.0$) for too many hours.

29 The required number of simulation runs was calculated based on a 95% confidence
 30 interval using the travel time on the weaving section, with a minimum of 10 simulation
 31 runs. For most weaving sections the lower bound of 10 simulation runs was set, here
 32 random seed 50 – 59 are used. For weaving section ID369 12 runs were required to obtain
 33 a statistical representative result, here seed 50 – 61 were used.

34 The Surrogate Safety Assessment Model (SSAM) was used to calculate the number of
 35 conflicts from the trajectory files. For that the conflict prediction thresholds in SSAM were
 36 set to 1.5 seconds for the TTC, 5.0 seconds for the PET, 30° for the rear-end angle and 85°
 37 for the crossing angle, as recommended by Gettman et al. (8). Similar values are used as
 38 maximum conflict filter values. In the micro-simulation some 'virtual' crashes occur,
 39 which are identified in SSAM with a TTC of 0 seconds. According to Gettman and Head
 40 (9) and Gettman et al. (8) these crashes should be removed before analysing the results.
 41 This is done by setting the lower bound for the TTC to 0.05 seconds using a filter. No filter
 42 is applied on the other surrogate safety measures, for the MaxS, DeltaS, DR, MaxD and
 43 MaxDeltaV values between -99 and 99 are accepted. Another filter will be applied on the
 44 conflict location, such that only the conflicts that occurred within the influence area of the
 45 weaving section are included, and not the conflicts that occurred on other locations in the

1 simulation model. This to have a fairer comparison to the crash rate, that is determined
2 based on crashes that occurred within the influence area.

3 From this the conflict numbers, conflicts rates (converted per number of vehicle
4 kilometres) and ranking positions were obtained.

5 (3) Based on the judgement of selected road safety experts:

6 A human factors analysis is an upcoming method for safety experts to be used when
7 predicting safety of a road section (21. 22). Hence some road safety experts were asked to
8 give their opinion on the weaving sections and rank them. Therefore, the experts received a
9 description of each weaving section, including traffic data such as intensities, HGV shares
10 and weaving percentages and maps and photographs. First each expert group member
11 made a ranking of the weaving sections. Thereafter the individual rankings were compared
12 and discussed in the expert group, such that one final ranking that all experts agreed on was
13 obtained.

14 (4) Based on crash prediction model (CPM) for symmetrical Dutch weaving sections
15 developed by Iliadi et al. (1):

16 The CPM model was developed to predict the number of crashes to occur on a symmetrical
17 weaving section in the Netherlands in a three-year period N :

$$18 \quad N = 4.46 \cdot 10^{-5} \cdot length^{0.46} \cdot AADT^{0.88} \cdot e^{0.35 lanes + 1.05 share - 1.667 loc} \quad (2)$$

19 In here, $length$ is the distance between the convergence and divergence gore, $AADT$ is
20 the annual average daily traffic expressed as vehicles per day, $lanes$ is the number of lanes
21 on the main freeway, $share$ is the percentage of car that is weaving during rush hours and
22 $location$ is the location of the weaving section related to the interchange (0 if inside and 1
23 if outside).

24 Note that the formula is for symmetrical weaving sections, and that the weaving section
25 ID454 is asymmetrical. However, due to absence of a Dutch CPM for asymmetrical
26 weaving sections the formula by Iliadi et al. was applied.

27 This resulted in the expected number of crashes. To have a fairer comparison to the other
28 rankings that are based on ratios, also the expected number of crashes was expressed as
29 ratio of the number of vehicle kilometres.

30 The strength of the relation between the rankings will be used to conclude whether
31 micro-simulations can be used in future for assessing safety of weaving sections. The relation
32 between safety estimations from micro-simulations and registered accidents will be assessed by
33 comparing the two safety rankings.

35 Results

36 This chapter describes the results of the corresponding rankings.

37
38 The final selection (Table 1) consists of nine weaving sections that have some common design
39 characteristics, but also have some differences as that is required to assess whether differences
40 result in different crash and conflict rates.

41
42 **Table 1: Selected weaving sections**

\	Location	Between	Road	Configuration	Length	Weaving	HGV
068	IC Heerenveen	Cloverleaf loops	Main	2+1	188.75	25%	14%

077	De Bilt – Maarssen	Junctions	Main	3+1	607.58	31%	9%
156	De Baars – Tilburg Noord	Interch. & junct.	Main	2+1	595.58	9%	14%

1

2 Rankings and Spearman Rank Correlation Coefficient

3 The rankings based on the four different methods explained in the previous section are presented in
4 table 2. Here ranking position 1 indicates an unsafe weaving section and position 9 indicates a
5 relatively safe weaving section.

6

7 Figure 3 visualises the ranking positions of the selected weaving sections based on the four
8 methods. It can be seen that all methods agree on that ID068 is safer than ID454, as an example.
9 However, there are large differences in judgement of for example ID256 and ID269.

10

11 **Table 2: Scores of the weaving sections on the four methods**

ID	Crash			VISSIM/SSAM			CPM			Experts
	Number	Ratio	Rank	Number	Ratio	Rank	Number	Ratio	Rank	Rank
068	5	1.3	6	5	4.2	7	2	0.4	9	5
077	34	1.1	7	112	13.2	4	46	1.5	2	3
156	12	0.7	9	1	0.1	9	15	0.9	4	7
173	128	1.6	5	30823	1409.4	1	107	1.3	3	2
256	19	9.5	1	4	5.8	5	1	0.4	8	8
269	4	3.7	3	2	5.6	6	1	0.7	6	9
369	31	7.3	2	147	116.7	2	2	0.5	7	6
412	52	1.1	8	3	0.3	8	36	0.8	5	4
454	94	2.6	4	678	69.5	3	61	1.7		1

12

13

1
2 **Figure 3: Ranking positions visualised**

3 The correlation between two rankings can be evaluated using the Spearman rank correlation
4 coefficient. This non-parametric test assesses the statistical dependence between two variables,
5 and is often used to assess how well the relationship between two variables can be described using
6 a monotonic function. The coefficient is calculated as

$$7 \quad \rho_s = 1 - \frac{6 \cdot \sum_{i=1}^n d_i^2}{n(n^2-1)} \quad (3)$$

8 where d_i is the difference between ranks for observation (i.e. weaving section) i and n represent
9 the number of observations (weaving sections) in the validation data set. Like Pearson's
10 correlation coefficient, the closer the coefficient is to ± 1 , the stronger the monotonic relationship
11 (8, 15).

12 Table 3 presents the Spearman Rank Correlation Coefficients and the corresponding
13 P-values.

14
15 **Table 3: Correlation coefficients (and P-values)**

	Crash rate	Experts	CPM
Experts	-0.300 (0.433)		
CPM	-0.367 (0.332)	0.683 (0.042)	
VISSIM & SSAM	0.567 (0.112)	0.467 (0.205)	0.300 (0.433)

1
2 The correlation between the VISSIM & SSAM ranking and the crash rate ranking is moderate,
3 similarly as the correlation of the VISSIM & SSAM ranking with the experts ranking. The
4 correlation between VISSIM & SSAM and the CPM is weak. The correlation between the experts
5 ranking and the CPM can be classified as strong. The negative correlation between the crash rate
6 and CPM ranking, suggesting a higher conflict rate corresponding to a lower expected number of
7 crashes in the crash prediction model, and vice versa, is not in line with the expectations. Similarly,
8 there is a negative correlation between the crash rate ranking and the experts ranking.
9 Except for the correlation between the experts and the CPM ranking, the correlations are not
10 significant at the 5% level.

11
12 When considering rankings based on crash and conflict numbers instead of ratios, all rank
13 correlations become stronger. This suggests that traffic intensity influences the number of crashes
14 and number of conflicts. It might be that due to the relation to traffic intensities a correlation
15 between VISSIM and SSAM and the crash counts is found, but that this is a spurious correlation
16 and that the relation between crashes and conflicts is not a causal relationship.

17 Especially the experts ranking has a very strong correlation with other number rankings,
18 which suggests that experts seem to focus more on the road characteristics than on exposure when
19 judging safety of weaving sections. Although the experts were asked to consider the exposure and
20 rank the weaving sections on the crash risk, it seems that their rankings are based more on crash
21 numbers than on crash rates.

22 23 **Sensitivity analysis**

24 There were several factors that influenced the obtained ranking and correlations, which are
25 discussed in this paper by means of a sensitivity analysis.

26 *Correlation coefficient* The Pearson Correlation Coefficient for ratios can be used as an alternative
27 to the Spearman Rank Correlation Coefficient, as for the first there is no need to first rank the
28 weaving sections and hence slight differences in ratio do not result in a large difference in ranking
29 position. For most rankings, the differences between the Pearson correlation coefficient and
30 Spearman Rank correlation coefficient were only minor. However, the correlation between
31 VISSIM & SSAM and the crash rate became weaker ($\rho_s = -0.158$), which is explained by the
32 very high conflict rate at ID173. The Pearson correlation between the CPM and the experts is
33 significant.

34 *Incomplete crash database* As it is generally known that the used BRON crash database is
35 incomplete, the UDLS database was used as an alternative. However, no major differences were
36 observed for correlations with BRON crash rates and UDLS crash rates.

37
38 *Sensitivity of the PET threshold* The initial PET projection threshold value in SSAM is 5.0
39 seconds, and this value was also used as maximum for filtering conflicts. According to Gettman et
40 al. (8) this value is selected based on a literature review. However, in literature also some lower
41 PET threshold values were proposed. Archer (23) describes that the PET should be below a
42 predetermined threshold value, which is typically 1 to 1.5 seconds. In his research the threshold
43 value was set to 1.5 seconds. Kraay et al. (24) concluded that in general on roads within urban area
44 only PET values below 1.0 seconds are perceived as possibly critical. Both have their focus in
45 interchanges and not on weaving sections. Hence the number of conflicts is calculated for these

1 PET threshold values, and for one extra value in between: 3 seconds.

2 It is seen that for lower PET filter values the correlation between the crash rate and VISSIM &
3 SSAM rate ranking is less strong.

4
5 *Sensitivity of the TTC threshold* SSAM uses an initial value of 1.5 seconds for the TTC threshold,
6 which is also proposed by amongst other Kraay et al. (24), recommended by Gettman et al. (8) and
7 used by Shahdah et al. (25). However, in literature also other values are proposed. Archer (23) uses
8 a threshold TTC of 3.5 seconds, and Kuang et al. (26) mentions that the TTC varies between 1.5
9 and 4.0 seconds. Assessing the effect of larger TTC filter values is not possible, as then the value
10 exceeds the projection threshold value and hence the conflict number does not change. Taking a
11 different projection threshold results in different projected conflicts and hence would result in an
12 unfair comparison. Hence sensitivity of the TTC filter threshold is assessed by taking maximum
13 TTC values of 0.5, 1.0 and 1.5 seconds. A stronger correlation between crash rate ranking and
14 conflict rate ranking is observed for lower filter values. This is in line with the expectations as the
15 lower the TTC value, the larger the likelihood that a conflict results in a crash.

16
17 *Effect of the Wiedemann Car-following model* Initially the Wiedemann99 car following model was
18 used in all simulations, as this was recommended by Fan et al. (27, p. 71). However, from the
19 VISSIM 9.0 manual (28, p. 247) it can be concluded that the Wiedemann74 model is better
20 suitable for modelling merging areas. When only changing the car-following model and leaving all
21 other VISSIM settings equal, it was found that for the Wiedemann99-model a correlation of 0.567
22 was found between the conflict rate ranking and crash rate ranking, and that this decreased to 0.300
23 for the Wiedemann74-model. More detailed traffic data on vehicle trajectories is required to
24 determine which model is best representing the real traffic behaviour.

25
26 *Effect of desired speed limit* It was found that for the initial VISSIM simulation models congested
27 speeds were used to determine the desired speed distributions. The desired speed distributions
28 were updated by using only the fastest half of the speeds measured by loop detectors, which
29 resulted in a weaker correlation of 0.433 between the crash rates and conflict rates.

30
31 *Effect of calibration on speeds* All previously presented results were based on a model that was
32 calibrated by a visual inspection and calibrating on vehicle intensities. However, including also a
33 calibration on vehicle speeds results in a model that is better representing the real traffic behaviour.
34 For that calibration, hourly simulated vehicle speeds from three simulation runs with seed 43 - 45
35 are compared with average hourly field speeds measured by loop detectors for working days in
36 September 2015. This resulted in changes in changes in the desired speed distributions and vehicle
37 inputs, to obtain a better correspondence between field and simulated traffic flow. After this extra
38 calibration procedure a correlation of -0.083 was found between simulated conflict rate ranking
39 and crash rate ranking, which is lower than the initial correlation. This is contradicting to the
40 hypothesis that a more extensive calibration leads to a stronger correlation.

41 Remarkable is that the conflict rate largely increased on weaving sections 077 and 412, where the
42 amount of congestion is increased by adding vehicles, and that the conflict rate decreased on
43 weaving section 173, where the evening peak congestion is decreased. This suggests that there is a
44 relation between the amount of congestion and the number of conflicts calculated by SSAM.

45
46 *Time, location and type* It is found that the times of the conflicts are reasonable corresponding to

1 the times of the crashes for weaving sections with a sufficient number of crashes. For weaving
2 sections with only a few crashes no clear correspondence is found, due to the stochasticity of the
3 occurrence of crashes. Correlation between conflict location and crash location was weak,
4 suggesting that SSAM is not good at predicting the location. As in the BRON crash database the
5 crash type is often registered as ‘unknown’ it was not possible to draw conclusions on the
6 predictability of the type.
7

8 **Conclusions and discussion**

9 Nine Dutch weaving sections were selected and ranked based on four criteria. A Spearman Rank
10 Correlation Coefficient was calculated between each of the rankings. A moderate correlation of
11 0.567 was observed between the conflict rate ranking and the crash rate ranking. However, this
12 correlation is not significant at the 5% significance interval. A stronger correlation of 0.683 was
13 observed between the CPM and experts ranking. Correlations between other rankings are weaker
14 or even negative.
15

16 There are multiple possible explanations for the differences between the rankings. It is generally
17 known that the BRON crash database is incomplete. However, consulting an alternative crash
18 database (UDLS) did not result in very different crash rates and correlations. The conflict rate
19 ranking is affected by both the VISSIM and SSAM settings. There are many input variables within
20 the VISSIM model, such as the desired vehicle speed, the car following model, the lane change
21 distance and many parameter settings that influence the vehicle trajectories and hence the number
22 of conflicts. Due to unavailability of precise data sometimes as good as possible available
23 alternatives are used. Furthermore, due to additional calibrating on speeds more congestion is
24 simulated at some locations, resulting in simulated traffic better representing the field, but also
25 resulting in many more conflicts at some congested locations and a weaker correlation. Hence it is
26 desired to get deeper insight in VISSIM parameter settings. Also the TTC and PET prediction and
27 filtering threshold values in SSAM affect the ranking. It should be noted that VISSIM and SSAM
28 only determine vehicle to vehicle conflicts, while also single-vehicle crashes are included in the
29 crash rates and CPM. This might lead to an unfair comparison. Furthermore, the road safety
30 experts ranked the weaving sections in only one hour, while much more time is spent on spent on
31 assessing the safety of the proposed design options as part of the design process. Lastly only a
32 small sample of only 9 weaving sections was used, so one exceptional weaving section largely
33 influences the correlation.

34 Furthermore, in this research weaving sections with clear variations in crash rates were selected.
35 However another strategy could be to select weaving sections with similar crash rates and
36 investigate whether this results in similar conflict rates. Furthermore, only one ranking of each
37 type was created, but it can be desirable to perform cross-validation such that multiple rankings of
38 a type are compared to multiple rankings of another type.

39 A possible application of VISSIM and SSAM is to compare multiple design alternatives when
40 (re)constructing a weaving section. Hence for one site multiple designs are compared. In this
41 research weaving sections at different types were compared, which thus differs from the proposed
42 application.
43

44 Hence, one should be very careful with using the number of conflicts calculated using VISSIM and
45 SSAM as (only) predictor for safety of Dutch weaving sections.

1 In other countries crash prediction models were developed and used frequently. Such a CPM for
2 symmetrical weaving sections in the Netherlands resulted in a weaker correlation to crash rates
3 than VISSIM and SSAM, but the correlation between the CPM and the experts is stronger ($\rho_s =$
4 0.683 , $P = 0.042$). Hence the CPM might be more appropriate for judging safety of a proposed
5 design for a weaving section, although it gives no details on the location and severity of the
6 conflicts and potential crashes.
